NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Fishman's Pulmonary Diseases and Disorders

Sixth Edition

Volume 1

EDITOR-IN-CHIEF

Michael A. Grippi, MD

Pulmonary, Allergy, and Critical Care Division
Department of Medicine
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania

EDITORS

Danielle E. Antin-Ozerkis, MD

Medical Director, Yale Center for Interstitial Lung Diseases
Associate Professor of Medicine
Section of Pulmonary, Critical Care and Sleep Medicine
Yale School of Medicine
New Haven, Connecticut

Charles S. Dela Cruz, MD, PhD

Associate Professor of Medicine
Section of Pulmonary, Critical Care and Sleep Medicine
Associate Professor of Microbial Pathogenesis
Director, Center of Pulmonary Infection Research and Treatment
Yale School of Medicine
New Haven, Connecticut

Robert M. Kotloff, MD

Craig and Elaine Dobbin/Nancy P. Blumenthal
Professor of Advanced Lung Disease
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania

Camille Nelson Kotton, MD

Associate Professor, Harvard Medical School
Clinical Director, Transplant and Immunocompromised Host
Infectious Diseases
Infectious Diseases Division, Massachusetts General Hospital
Boston, Massachusetts

Allan I. Pack, MBChB, PhD

John Miclot Professor of Medicine
Division of Sleep Medicine
Department of Medicine
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania

Library of Congress Cataloging-in-Publication Data

Names: Grippi, Michael A., editor.
Title: Fishman's pulmonary diseases and disorders / editor-in-chief, Michael A. Grippi ; co-editors, Danielle E. Antin-Ozerkis, Charles S. Dela Cruz, Robert M. Kotloff, Camille N. Kotton,
Allan I. Pack
Other titles: Pulmonary diseases and disorders
Description: Sixth edition. | New York : McGraw-Hill Education, [2023] | Includes bibliographical references and index. | Summary: "A presentation of pulmonary and critical care medicine with the underlying basic and applied science upon which the clinical material is based. The book includes relevant respiratory biology and underlying cellular and molecular mechanisms, and incorporates of a number of videos designed to complement and, at times, accentuate information contained within the text"– Provided by publisher.
Identifiers: LCCN 2021052087 | ISBN 9781260473988 (hardcover ; set ; alk. paper) | ISBN 9781260474060 (ebook)
Subjects: MESH: Lung Diseases
Classification: LCC RC756 | NLM WF 600 | DDC 616.2/4–dc23/eng/20220510
LC record available at https://lccn.loc.gov/2021052087

This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.

DEDICATION

This book is dedicated to the many clinicians worldwide who have devoted themselves to caring for those affected by SARS-CoV-19 and to the scientists who developed vaccines and therapeutic modalities directed against the virus.

MAG: To my wife, Barbara, and to our daughters, Kristen and Amy, for their steadfast support over the years, and to their families—Emily, Ali, Sawyer, Sophie, Levi, and Kieran.

DAO: To my husband, Eric, and our daughters, Orly and Daya. If you are going to spend a pandemic with anyone, you might as well laugh a lot. And to my patients, from whom I learn every day.

CDC: I would like to thank my family, friends, and all the mentors in pulmonary and critical care medicine who helped support me throughout my career. I would also like to thank my patients, from whom I have learned so much and who have been the motivation for my current work.

RMK: To my wife, Debbie, and my sons, Eric, Brian, and Ethan, for their unwavering love and support. And to the memory of my parents, Jean and Leon Kotloff, for instilling in me the principles by which I live my life and practice my profession.

CNK: Thanks to my husband, Darrell Kotton, and to our wonderful sons, David and Benjamin, for their thoughtfulness and support, especially as we navigated our family through the peaks of the COVID-19 pandemic. And thanks to my patients over the years, who have taught me so much about medicine, but also about resilience, optimism, and hope.

AIP: To my very supportive wife, Frances; my long-collaborating Administrative Assistant, Daniel Barrett; my four children, Alison, Angela, Andrew, and Allan Junior; and our 11 grandchildren.

CONTENTS

Contributors . . . xiii
Preface . . . xxix

VOLUME 1

PART 1: Perspectives

1 **Milestones in the History of Pulmonary Medicine** . . . 2
Michael A. Grippi

PART 2: Scientific Basis of Lung Function in Health and Disease

SECTION 1 Genetic, Cellular, and Structural Basis of Normal Lung Function

2 **Functional Design of the Human Lung for Gas Exchange** . . . 22
Matthias Ochs
3 **The Respiratory Muscles** . . . 65
Ghislaine Gayan-Ramirez / Daniel Langer / Marc Decramer
4 **Molecular Regulation of Lung Development** . . . 76
Wellington V. Cardoso / Ying Yang / Jining Lu
5 **Pulmonary Surfactant and Disorders of Surfactant Homeostasis** . . . 90
Jeffrey A. Whitsett / James P. Bridges / Timothy E. Weaver
6 **Mucociliary Clearance** . . . 101
Thomas W. Ferkol / John D. Dickinson / Burton F. Dickey
7 **The Genetic Basis of Respiratory Disorders** . . . 118
Micheala A. Aldred
8 **Stem Cells and Respiratory Disease: Prospects for the Future** . . . 135
Konstantinos-Dionysios Alysandratos / Michael J. Herriges / Darrell N. Kotton
9 **Personalized Pulmonary Medicine** . . . 145
Benjamin A. Raby / Kelan G. Tantisira

SECTION 2 Physiological Principles of Normal Lung Function

10 **Pulmonary Mechanics** . . . 161
Allan I. Pack / Michael A. Grippi
11 **Control of Ventilation** . . . 173
Frank J. Jacono / Atul Malhotra
12 **Sleep and Circadian Rhythms** . . . 183
Allan I. Pack
13 **The Pulmonary Circulation** . . . 193
Robert Naeije
14 **Ventilation, Pulmonary Blood Flow, and Ventilation–Perfusion Relationships** . . . 211
Peter D. Wagner
15 **Blood Gas Transport** . . . 224
Adrian Shifren / Robert A. Klocke
16 **Diffusion, Chemical Reactions, and Diffusing Capacity** . . . 229
Robert A. Klocke / Adrian Shifren
17 **Acid–Base Balance** . . . 236
Stanley Goldfarb
18 **Aging of the Respiratory System** . . . 248
Edward J. Campbell / Corrine R. Kliment

SECTION 3 Lung Immunology

19 **Innate and Adaptive Immunity in the Lung** . . . 262
Clemente J. Britto / Charles S. Dela Cruz
20 **Macrophages and Lymphocytes in the Lung** . . . 277
Katrina E. Traber / Joseph P. Mizgerd / David M. Center
21 **Mast Cells and Eosinophils** . . . 290
Edward S. Schulman / Peter H.S. Sporn / Amali E. Samarasinghe
22 **Antibody-Mediated Lung Defenses and Humoral Immunodeficiency** . . . 313
Homer L. Twigg III

SECTION 4 Lung Injury and Repair

23 **T Cell Responses in the Lung** . . . 329
Lauren Cohn
24 **Chemokines, Adipokines, and Growth Factors in the Lung** . . . 339
Marcus W. Butler / Paul McLoughlin / Michael P. Keane
25 **Redox Signaling and Oxidative Stress in Lung Diseases** . . . 356
Jessy Deshane / Victor J. Thannickal
26 **Fibroblasts in Lung Homeostasis and Disease** . . . 376
Yong Zhou / Victor J. Thannickal

PART 3: Symptoms and Signs of Respiratory Disease

SECTION 5 Clinical Approach to the Patient

27 **Approach to the Patient with Respiratory Symptoms** . . . 394
Michael A. Grippi / Jeffrey P. Callen

SECTION 6 Diagnostic Procedures

28 **Modern Approach to Thoracic Imaging Diagnosis** . . . 433
Eduardo J. Mortani Barbosa Jr. / Leonid Roshkovan
29 **Thoracic Ultrasonography** . . . 501
Andrew Weber / Fiore Mastroianni / Paul H. Mayo
30 **Physiologic and Metabolic Assessment of Pulmonary Disorders Using Conventional Imaging Techniques and Positron Emission Tomography** . . . 511
Ghassan El-Haddad / Søren Hess / Abass Alavi
31 **Pulmonary Function Testing** . . . 544
Michael A. Grippi / Gregory Tino

AL GRAWANY

32 **Principles and Application of Cardiopulmonary Exercise Testing** . . . 579
Marco Guazzi / Alice Moroni

33 **Diagnostic Bronchoscopy, Transthoracic Needle Biopsy, and Related Procedures** . . . 597
David M. DiBardino / Daniel H. Sterman / Anil Vachani

34 **Interventional Pulmonology** . . . 620
Daniel G. Dunlap / Andrew R. Haas / Daniel H. Sterman

35 **Diagnostic Thoracic Surgical Procedures: Thoracoscopy, VATS, RATS, and Thoracotomy** . . . 632
Robert E. Merritt

36 **Evaluation of Respiratory Impairment and Disability** . . . 636
Lisa Ruvuna / Akshay Sood

PART 4: Obstructive Lung Diseases

SECTION 7 Chronic Obstructive Pulmonary Disease

37 **Pathology of Chronic Obstructive Pulmonary Disease: Diagnostic Features and Differential Diagnosis** . . . 650
Joanne L. Wright / Andrew Churg

38 **Chronic Obstructive Pulmonary Disease: Epidemiology, Pathophysiology, Pathogenesis** . . . 664
Takudzwa Mkorombindo / Mark T. Dransfield

39 **Chronic Obstructive Pulmonary Disease and α1-Antitrypsin Deficiency** . . . 683
Darrell N. Kotton / Andrew A. Wilson

40 **Course and Treatment of Chronic Obstructive Pulmonary Disease** . . . 693
M. Bradley Drummond / Robert A. Wise

41 **Cigarette Smoking, Smoking Cessation, and Electronic Cigarettes** . . . 708
Stephen R. Baldassarri / Stephen I. Rennard

42 **Rehabilitation in Chronic Obstructive Pulmonary Disease and Other Respiratory Disorders** . . . 725
Andrew L. Ries / Duc M. Ha

SECTION 8 Asthma

43 **The Biology of Asthma** . . . 734
Geoffrey L. Chupp / Matthew C. Bell / William W. Busse

44 **The Epidemiology of Asthma** . . . 750
Kathleen A. Lee-Sarwar / Scott T. Weiss / Augusto A. Litonjua

45 **Asthma: Clinical Presentation and Management** . . . 767
Omar S. Usmani / Peter J. Barnes

46 **Allergic Bronchopulmonary Aspergillosis (Mycosis) and Severe Asthma with Fungal Sensitivity** . . . 785
Geoffrey L. Chupp

SECTION 9 Other Obstructive Disorders

47 **Upper Airway Obstruction in Adults** . . . 794
Erin DeBiasi / Christine Won / Meir Kryger

48 **Cystic Fibrosis** . . . 815
Judith A. Voynow / Andrea Kelly / Flora K. Szabo / Thomas F. Scanlin

49 **Bronchiolitis** . . . 842
Gary R. Epler

50 **Bullous Lung Disease** . . . 849
Fernando J. Martinez

51 **Bronchiectasis** . . . 862
Gregory Tino

PART 5: Interstitial and Inflammatory Lung Diseases

52 **Interstitial Lung Disease: A Clinical Overview and General Approach** . . . 872
Aditi Mathur / Danielle E. Antin-Ozerkis

53 **Systemic Sarcoidosis** . . . 891
Edward S. Chen

54 **Idiopathic Pulmonary Fibrosis** . . . 915
Tanzira Zaman / Giuliana Cerro Chiang / Paul W. Noble

55 **Idiopathic Interstitial Pneumonias Other Than Idiopathic Pulmonary Fibrosis** . . . 932
Kelly M. Hager / Ami Rubinowitz / Mridu Gulati

56 **Hypersensitivity Pneumonitis** . . . 956
Prerna Mota / Richard I. Enelow

57 **Radiation Pneumonitis** . . . 966
James H. Laird / Kenneth B. Roberts / Roy H. Decker / Henry S. Park

58 **Pulmonary Manifestations of the Collagen Vascular Diseases** . . . 987
Kevin P. Toole / Gregory P. Cosgrove

59 **Pulmonary Langerhans Cell Histiocytosis** . . . 1006
Sergio Harari / Davide Elia / Joel Moss / Abdellatif Tazi

60 **Pulmonary Lymphangioleiomyomatosis** . . . 1015
Arnold S. Kristof / Joel Moss

61 **Diffuse Cystic Lung Diseases** . . . 1030
Nishant Gupta / Tami J. Bang / Kathryn A. Wikenheiser-Brokamp

62 **Benign Metastasizing Leiomyoma** . . . 1054
Gustavo Pacheco-Rodriguez / Olga I. Astapova / Stephen R. Hammes / Joel Moss

63 **Depositional Lung Disorders: Amyloidosis, Pulmonary Calcification, and Pulmonary Ossification** . . . 1065
Robert J. Homer / Christopher Gange / Natalia Neparidze

PART 6: Drug-Induced Lung Diseases

64 **Pulmonary Toxicity Related to Systemic Treatments for Cancer** . . . 1074
Jennifer D. Possick / Erin DeBiasi / Lynn T. Tanoue

65 **Drug-induced Pulmonary Disease Due to Nonchemotherapeutic Agents** . . . 1100
Hilary C. Cain

66 **Lung Injury Associated with Recreational Drug Use** . . . 1119
Timothy E. Albertson / Patrick Mangialardi / James A. Chenoweth / Susan Murin

PART 7: Other Infiltrative and Airspace Disorders

67 **The Lungs in Patients with Inborn Errors of Metabolism** . . . 1136
Timothy Craig Allen

68 **Alveolar Hemorrhage Syndromes** 1144
Joseph P. Lynch, III / Michael C. Fishbein / Tisha S. Wang

69 **Aspiration-Related Pulmonary Disorders** 1164
Paul E. Marik

70 **Pulmonary Alveolar Proteinosis Syndrome** 1175
Bruce C. Trapnell / Cormac McCarthy / Brenna Carey

71 **Eosinophilic Lung Diseases** 1186
Lauren Cohn / Carolyn L. Rochester / Brian J. Clark

72 **Pulmonary Arterial Hypertension** 1211
Nick H. Kim / Jess Mandel / Kimberly A. Smith / Jason X.-J. Yuan

PART 8: Disorders of the Pulmonary Circulation

73 **Pulmonary Thromboembolic Disease** 1258
Timothy M. Fernandes / Peter F. Fedullo

74 **Pulmonary Vasculitis** 1287
Rodrigo Cartin-Ceba / Ulrich Specks

75 **Pulmonary Arteriovenous Malformations** 1306
Tyler J. Peck / Josanna M. Rodriguez-Lopez

PART 9: Disorders of the Pleural Space

76 **Nonmalignant Pleural Effusions** 1320
Christopher M. Kapp / David Feller-Kopman

77 **Malignant Pleural Effusions** 1339
Jeffrey C. Thompson / Kevin C. Ma

78 **Malignant Mesothelioma and Other Primary Pleural Tumors** 1351
Daniel H. Sterman / Edmund K. Moon / Keshav Mangalick / Leslie A. Litzky

79 **Pneumothorax** 1375
Rodolfo A. Estrada / Jay I. Peters / Nilam J. Soni / Philip G. Ong

VOLUME 2

PART 10: Diseases of the Mediastinum

80 **Nonneoplastic Disorders of the Mediastinum** 1398
Luis F. Tapias / Cameron D. Wright

81 **Congenital Cysts of the Mediastinum: Bronchopulmonary Foregut Anomalies** 1412
Erik E. Lewis / Daniel P. McCarthy / Malcolm M. DeCamp

82 **Primary Benign and Malignant Neoplasms of the Mediastinum** 1423
Natalie S. Lui / Joseph B. Shrager

PART 11: Disorders of the Chest Wall, Diaphragm, and Spine

83 **Nonmuscular Diseases of the Chest Wall** 1440
George E. Tzelepis / F. Dennis McCool

84 **Effects of Neuromuscular Diseases on Ventilation** 1459
Gerard Joseph Criner / Nathaniel Marchetti

PART 12: Occupational and Environmental Disorders

SECTION 10 Occupational Disorders

85 **Asbestos-Related Lung Disease** 1488
William N. Rom / Jun-Chieh J. Tsay

86 **Chronic Beryllium Disease and Hard-Metal Lung Diseases** 1502
Shweta Sood / Mary Elizabeth Kreider

87 **Coal Workers' Lung Diseases and Silicosis** 1513
Robert C. Stansbury / Rahul G. Sangani / John E. Parker

88 **Occupational Asthma, Byssinosis, and Industrial Bronchitis** 1532
Shu-Yi Liao / David C. Christiani

SECTION 11 Environmental Disorders

89 **Indoor and Outdoor Air Pollution** 1539
Coralynn Sack / Joel D. Kaufman

90 **Acute and Chronic Responses to Toxic Inhalations** 1559
Austin J. Jolly / David A. Schwartz

91 **High-Altitude Physiology and Clinical Disorders** 1581
Kingman P. Strohl / Cynthia M. Beall / Nikolaus C. Netzer

92 **Diving Physiology and Dysbarism** 1593
Christopher E. Winstead-Derlega / Richard E. Moon

93 **Thermal Lung Injury and Acute Smoke Inhalation** 1603
Perenlei Enkhbaatar

PART 13: Pulmonary Complications of Nonpulmonary Disorders

94 **Noninfectious Pulmonary Complications of Hematopoietic Stem Cell and Solid Organ Transplantation** 1620
Hemang Yadav / Steve G. Peters / Robert M. Kotloff

95 **Pulmonary Complications of Sickle Cell Disease** 1644
Roberto F. Machado / Mark T. Gladwin

96 **Pulmonary Disorders and Pregnancy** 1663
Debasree Banerjee / Andrew T. Levinson / Jeffrey Mazer / Ghada Bourjeily

97 **Pulmonary Complications of Intra-abdominal Disease** 1685
Hilary M. DuBrock / Sonja D. Bartolome

PART 14: Sleep and Sleep Disorders

98 **Sleep Apnea Syndromes: Central and Obstructive** 1700
Grace W. Pien / Ilene M. Rosen / Barry G. Fields

99 **Sleep-related Hypoventilation Syndromes** 1751
Jorge I. Mora / Richard J. Schwab

100 **Changes in the Cardiorespiratory System During Sleep** 1765
Indira Gurubhagavatula / Susheel P. Patil

101 **Differential Diagnosis and Evaluation of Sleepiness** 1773
Sritika Thapa / Mithu Sen / Meir Kryger

AL GRAWANY

PART 15: Surgical Aspects of Pulmonary Medicine

102 **Perioperative Respiratory Considerations in the Surgical Patient** 1786
Horace M. DeLisser / Michael A. Grippi

103 **Acute Respiratory Failure in the Surgical Patient** 1801
Robert M. Kotloff

104 **Thoracic Trauma** 1816
Seth A. Bellister / Bradley M. Dennis

105 **Developmental Disorders of the Lung** 1824
Himanshu Deshwal / Subha Ghosh

106 **Lung Transplantation** 1843
Ramsey R. Hachem

PART 16: Cancer and Other Malignancies of the Lungs

107 **Genetic and Molecular Changes in Lung Cancer: Prospects for a Personalized Pharmacologic Approach to Treatment** 1864
Howard Y. Li / Jeffrey A. Kern

108 **Epidemiology of Lung Cancer** 1882
Lynn T. Tanoue / Charles S. Dela Cruz

109 **Lung Cancer Screening** 1904
Humberto K. Choi / Peter J. Mazzone

110 **Approach to the Patient with Pulmonary Nodules** 1911
Moiz Salahuddin / David E. Ost

111 **The Pathology of Bronchogenic Carcinoma** 1929
Leslie A. Litzky

112 **Clinical Evaluation, Diagnosis, and Staging of Lung Cancer** 1950
A. Cole Burks / M. Patricia Rivera

113 **Treatment of Non–Small-Cell Lung Cancer: Surgery** 1964
John K. Waters / Scott I. Reznik

114 **Treatment of Non–Small-Cell Lung Cancer: Chemotherapy and Immunotherapy** 1977
Laurie L. Carr

115 **Treatment of Non–Small-Cell Lung Cancer: Radiation Therapy** 1992
Joseph A. Miccio / Mitchell Machtay

116 **Small Cell Lung Cancer: Diagnosis, Treatment, and Natural History** 2002
Jonathan E. Dowell / Benjamin J. Drapkin / David E. Gerber / David H. Johnson

117 **Uncommon Tumors of the Lung** 2022
Karen Rodriguez / Gerald F. Abbott

118 **Extrapulmonary Syndromes Associated with Lung Tumors** 2031
Nicholas J. Pastis / Nichole T. Tanner / Gerard A. Silvestri

119 **Lymphoproliferative Diseases Involving the Lung** 2045
Venerino Poletti / Sara Piciucchi / Silvia Asioli

PART 17: Infectious Diseases of the Lungs

SECTION 12 General Concepts

120 **Pulmonary Clearance of Infectious Agents** 2070
Theodore J. Standiford / Gary B. Huffnagle

121 **The Lung Microbiome** 2088
John E. McGinniss / Joshua M. Diamond

122 **Approach to Pulmonary Infection in the Immunocompetent Host** 2099
Megan Rose Curtis / Tulip Ajit Jhaveri / Camille Nelson Kotton

123 **Approach to Pulmonary Infection in the Immunocompromised Host** 2127
Matthew B. Roberts / Camille Nelson Kotton

124 **Microbial Virulence Factors in Pulmonary Infections** 2154
Carl D. Britto / Gregory P. Priebe / Gerald B. Pier

125 **Principles of Antibiotic Use and the Selection of Empiric Therapy for Pneumonia** 2161
Girish B. Nair / Michael S. Niederman

SECTION 13 Common Syndromes in Pulmonary Infectious Diseases

126 **Viral Infections of the Lung and Respiratory Tract** 2181
John Treanor

127 **Aspiration, Empyema, Lung Abscesses, and Anaerobic Infections** 2203
Kyle B. Enfield / Costi D. Sifri

128 **Acute Bronchitis and Community-Acquired Pneumonia** 2223
James M. Walter / Richard G. Wunderink

129 **Nosocomial Pneumonia, Including Ventilator-associated Pneumonia** 2243
Andrew T. Roth / Marin H. Kollef

SECTION 14 Major Pathogens in Pulmonary Infections

130 **Tuberculosis** 2256
Akash Gupta / Karen R. Jacobson

131 **Pulmonary Diseases Due to Nontuberculous Mycobacteria** 2278
John S. Albin / Rocio M. Hurtado

132 ***Aspergillus, Candida,* and Other Opportunistic Pulmonary Mycoses** 2290
Georgios Chamilos / Dimitrios P. Kontoyiannis

133 **Cryptococcosis and the Endemic Mycoses: *Histoplasma, Blastomyces,* and *Coccidioides*** 2319
Marwan M. Azar / Nathan C. Bahr / Joshua Malo / Chadi A. Hage

134 ***Pneumocystis* Pneumonia** 2353
Eliezer Zachary Nussbaum / Marwan M. Azar

135 **Protozoan Infections of the Thorax** 2375
Louise C. Ivers / Edward T. Ryan

136 **Helminthic Diseases of the Lung** 2388
Ricardo M. La Hoz / James B. Cutrell

137 **Nocardiosis and Actinomycosis** 2401
Daniel N. Maxwell / Reuben J. Arasaratnam / Alejandro Restrepo / Tara M. Babu

138 **Zoonotic and Environmental Bacterial Pneumonias** 2421
Camille Nelson Kotton / Howard M. Heller

PART 18: Respiratory Failure

139 **Respiratory Failure: An Overview** 2436
Michael A. Grippi

SECTION 15 Lung Failure

140 **Acute Respiratory Distress Syndrome: Pathogenesis** 2447
Asha N. Chesnutt / Michael A. Matthay

141 **Acute Respiratory Distress Syndrome: Clinical Features, Management, and Outcomes** 2459
John P. Reilly / Jason D. Christie

SECTION 16 Respiratory Pump Failure

142 **Chronic Hypercapnic Respiratory Failure: Pathogenesis and Management** 2488
Jennifer J. Dorsch / Jorge I. Mora

SECTION 17 Management and Therapeutic Interventions

143 **Oxygen Therapy and Toxicity** 2507
Matthew Wemple / Erik R. Swenson

144 **Pulmonary Pharmacotherapy** 2523
Karen J. Tietze / Scott Manaker

145 **Intubation and Upper Airway Management** 2543
Joshua H. Atkins / Christopher H. Rassekh

146 **Hemodynamic and Respiratory Monitoring in Acute Respiratory Failure** 2559
Hari M. Shankar / Brian J. Anderson

147 **Principles of Mechanical Ventilation** 2573
Martin J. Tobin

148 **Principles of Noninvasive Pressure-targeted Ventilation** 2588
Bernardo Selim / Janet Hilbert / Henry K. Yaggi

149 **Extracorporeal Membrane Oxygenation (ECMO) in Acute Respiratory Failure** 2610
Asad Ali Usman / Jacob Gutsche

150 **Nutrition in Pulmonary Disease** 2634
Tachira Tavarez / David S. Seres

151 **Diagnosis and Treatment of Pain, Agitation, and Delirium in the Intensive Care Unit** 2643
Niall T. Prendergast / Timothy D. Girard / Nathan E. Brummel

152 **Ethics and Palliative Care in Critical Care Units** 2659
Joshua B. Kayser / Horace M. DeLisser

Boston, Massachusetts
Chapter 131

Micheala A. Aldred, PhD
Professor of Medicine
Catherine and Lowe Berger and Pauline L. Ford Chair of Pulmonary Medicine
Department of Medicine
Division of Pulmonary, Critical Care, Sleep & Occupational Medicine
Indiana University School of Medicine
Indianapolis, Indiana
Chapter 7

Timothy Craig Allen, MD, JD, FCAP
Professor and Chair
Department of Pathology
The University of Mississippi Medical Center
Jackson, Mississippi
Chapter 67

Konstantinos-Dionysios Alysandratos, MD, PhD
Assistant Professor of Medicine
The Pulmonary Center and Department of Medicine
Boston University School of Medicine
Attending Physician
Department of Medicine
Boston Medical Center
Boston, Massachusetts
Chapter 8

Brian J. Anderson, MD, MSCE
Assistant Professor of Medicine
Department of Medicine
Division of Pulmonary, Allergy & Critical Care Medicine
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 146

Danielle E. Antin-Ozerkis, MD
Medical Director, Yale Center for Interstitial Lung Diseases
Associate Professor of Medicine
Section of Pulmonary, Critical Care and Sleep Medicine
Yale School of Medicine
New Haven, Connecticut
Chapter 52

Reuben J. Arasaratnam, MD, MPH
Staff Physician, Section of Infectious Diseases
VA North Texas Health Care System
Assistant Professor of Medicine
Division of Infectious Diseases and Geographic Medicine
UT Southwestern Medical Center
Dallas, Texas
Chapter 137

Silvia Asioli, MD
Team Leader of Haematopathology and Consultant
Department of Anatomic Pathology
Ospedale GB Morgagni
Forlì, Italy
Chapter 119

Olga I. Astapova, MD, PhD
Assistant Professor, Department of Medicine
Division of Endocrinology
University of Rochester Medical Center
University of Rochester School of Medicine and Dentistry
Rochester, New York
Chapter 62

Joshua H. Atkins, MD, PhD, FASA
Associate Professor of Anesthesiology & Critical Care
Department of Anesthesiology and Critical Care
Perelman School of Medicine at the University of Pennsylvania
Attending Physician, Co-Chair Airway Safety Committee
Director of Anesthesia for Head and Neck Surgery
Medical Director In-situ Simulation
Department of Anesthesiology and Critical Care
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 145

Marwan M. Azar, MD
Assistant Professor of Medicine/Infectious Diseases
Section of Infectious Diseases
Department of Internal Medicine
Yale University School of Medicine
Department of Laboratory Medicine
Yale University School of Medicine
New Haven, Connecticut
Chapter 134

Tara M. Babu, MD, MSCI
Acting Assistant Professor
Department of Medicine
Division of Allergy & Infectious Diseases
University of Washington
Seattle, Washington State
Chapter 137

Nathan C. Bahr, MD
Associate Professor
Department of Internal Medicine
Division of Infectious Diseases
University of Kansas Medical Center
Kansas City, Kansas
Chapter 133

AL GRAWANY

Stephen R. Baldassarri, MD, MHS
Department of Internal Medicine
Section of Pulmonary, Critical Care, and Sleep Medicine
Yale School of Medicine
New Haven, Connecticut
Chapter 41

Debasree Banerjee, MD, MS
Assistant Professor, Department of Medicine, Brown University
Director, Critical Care Consult, Rhode Island Hospital
Providence, Rhode Island
Chapter 96

Tami J. Bang, MD
Assistant Professor
Department of Radiology, Division of Cardiothoracic Imaging
University of Colorado—Anschutz Medical Campus
Aurora, Colorado
Chapter 61

Eduardo J. Mortani Barbosa Jr., MD
Assistant Professor of Radiology
Director of Thoracic CT modality
Department of Radiology
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 28

Peter J. Barnes, DM, DSc, FRCP, FCCP, FMedSci, FRS
Professor of Thoracic Medicine
National Heart & Lung Institute, Imperial College London
London, United Kingdom
Chapter 45

Sonja D. Bartolome, MD
Professor, Department of Internal Medicine, University of Texas Southwestern Medical Center
Dallas, Texas
Chapter 97

Cynthia M. Beall, PhD
Professor, Anthropology
Case Western Reserve University
Cleveland, Ohio
Chapter 91

Matthew C. Bell, MD
Assistant Professor of Medicine and Pediatrics
Department of Pediatrics
Division of Allergy & Immunology
University of Arkansas for Medical Sciences
Arkansas Children's Hospital
Little Rock, Arkansas
Chapter 43

Seth A. Bellister, MD
Department of Trauma and Acute Care Surgery
Christus Mother Frances Hospital
Tyler, Texas
Chapter 104

Ghada Bourjeily, MD
Professor of Medicine
Warren Alpert Medical School of Brown University
Associate Chief for Academic Advancement and Research in Women's Services
Women's Medicine Collaborative of Lifespan
Department of Medicine
The Miriam Hospital
Providence, Rhode Island
Chapter 96

James P. Bridges, PhD
Associate Professor
Department of Medicine
National Jewish Health
Denver, Colorado
Chapter 5

Carl D. Britto, MBBS, DPhil
Clinical Fellow in Pediatrics, Harvard Medical School
Resident in Pediatrics, Department of Pediatrics
Boston Children's Hospital
Boston, Massachusetts
Chapter 124

Clemente J. Britto, MD
Assistant Professor of Medicine
Associate Director, Yale Adult Cystic Fibrosis Program
Department of Internal Medicine
Division of Pulmonary, Critical Care and Sleep Medicine
Yale University School of Medicine
New Haven, Connecticut
Chapter 19

Nathan E. Brummel, MD, MSCI, FCCM
Associate Professor of Medicine
Department of Internal Medicine
Division of Pulmonary, Critical Care, and Sleep Medicine
The Ohio State University Columbus, Ohio
Chapter 151

A. Cole Burks, MD
Assistant Professor of Medicine
Division of Pulmonary and Critical Care Medicine
University of North Carolina at Chapel Hill
Interventional Pulmonology, University of North Carolina Medical Center
Chapel Hill, North Carolina
Chapter 112

William W. Busse, MD
Emeritus Professor of Medicine
Department of Medicine
Division of Allergy, Pulmonary and Critical Care Medicine
University of Wisconsin School of Medicine and Public Health
Madison, Wisconsin
Chapter 43

Marcus W. Butler, MD, FRCPI
Associate Professor
University College Dublin School of Medicine
Consultant Respiratory Physician
St. Vincent's University Hospital
Dublin, Ireland
Chapter 24

Hilary C. Cain, MD, MS
Associate Professor of Medicine
Section of Pulmonary, Critical Care and Sleep Medicine
Yale School of Medicine
New Haven, Connecticut
Section Chief, Pulmonary Medicine
VA Connecticut Healthcare System
West Haven, Connecticut
Chapter 65

Jeffrey P. Callen, MD, FACP, MAAD, MACR
Professor of Medicine (Dermatology)
Chief, Division of Dermatology
University of Louisville School of Medicine
Louisville, Kentucky
Chapter 27

Edward J. Campbell, MD
Heredilab, Inc.
Salt Lake City, Utah
Chapter 18

Wellington V. Cardoso, MD, PhD
Professor of Medicine and Genetics & Development
Columbia Center for Human Development
Department of Medicine
Columbia University Medical Center
New York, New York
Chapter 4

Brenna Carey, MS, PhD
Assistant Professor of Medicine
Department of Pediatrics, University of Cincinnati
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio
Chapter 70

Laurie L. Carr, MD
Associate Professor of Medicine
Division of Oncology
National Jewish Health and University of Colorado
Denver, Colorado
Chapter 114

Rodrigo Cartin-Ceba, MD, MSc
Professor of Medicine, Mayo Clinic College of Medicine and Science
Consultant, Department of Medicine
Division of Pulmonary Medicine, Mayo Clinic
Phoenix, Arizona
Chapter 74

David M. Center, MD
Gordon and Ruth Snider Professor of Pulmonary Medicine
Associate Provost for Translational Research
Professor of Medicine
Department of Medicine
Boston University
Chief, Pulmonary, Allergy, Sleep and Critical Care Medicine
Boston Medical Center
Boston, Massachusetts
Chapter 20

Georgios Chamilos, MD
Professor of Medicine
Department of Internal Medicine
School of Medicine, Stavrakia, Voutes
University of Crete Heraklion
Crete, Greece
Chapter 132

Giuliana Cerro Chiang, MD
Fellow in Pulmonary & Critical Care Medicine
Department of Medicine
Cedars-Sinai Medical Center
Los Angeles, California
Chapter 54

Edward S. Chen, MD
Assistant Professor
Division of Pulmonary and Critical Care Medicine
Johns Hopkins University School of Medicine
Attending Physician, Department of Medicine
Division of Pulmonary and Critical Care Medicine
Johns Hopkins Hospital
Baltimore, Maryland
Chapter 53

James A. Chenoweth, MD, MAS
Assistant Professor, Emergency Medicine
Department of Emergency Medicine
University of California, Davis
Sacramento, California
Veterans Administration Northern
Department of Medicine California Health Care System
Mather, California
Chapter 66

Asha N. Chesnutt, MD
The Oregon Clinic
Pulmonary, Critical Care & Sleep Medicine
Portland, Oregon
Chapter 140

Humberto K. Choi, MD
Assistant Professor of Medicine of Lerner College of Medicine of Case Western Reserve University
Respiratory Institute, Cleveland Clinic
Cleveland, Ohio
Chapter 109

David C. Christiani, MD, MPH, MS
Elkan Blout Professor of Environmental Genetics
Department of Environmental Health
Harvard T.H. Chan School of Public Health
Professor of Medicine
Harvard Medical School
Physician, Pulmonary and Critical Care Division
Department of Medicine
Massachusetts General Hospital
Boston, Massachusetts
Chapter 88

Jason D. Christie, MD, MSCE
Professor of Medicine and Epidemiology
Division of Pulmonary, Allergy, and Critical Care
Department of Medicine
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 141

Geoffrey L. Chupp, MD
Professor of Medicine
Yale School of Medicine
Director, Yale Center for Asthma and Airway Disease
Director, Pulmonary Function Laboratory, Yale New Haven Hospital
New Haven, Connecticut
Chapters 43 and 46

Andrew Churg, MD, PhD
Professor of Pathology, University of British Columbia Pathologist
Vancouver General Hospital
Vancouver, British Columbia, Canada
Chapter 37

Brian J. Clark, MD
Assistant Professor, Section of Pulmonary, Critical Care and Sleep Medicine
Yale School of Medicine
New Haven, Connecticut
VA Connecticut Healthcare System
West Haven, Connecticut
Chapter 71

Lauren Cohn, MD
Associate Professor
Department of Medicine, Section of Pulmonary, Critical Care and Sleep Medicine
Yale School of Medicine, New Haven, Connecticut
VA Connecticut Healthcare System
West Haven, Connecticut
Chapters 23 and 71

Gregory P. Cosgrove, MD
Associate Professor
Department of Medicine
Division of Pulmonary Sciences and Critical Care Medicine
University of Colorado—Anschutz Medical Campus
Denver, Colorado
Chapter 58

Gerard Joseph Criner, MD
Chair and Professor of Thoracic Medicine and Surgery
Department of Thoracic Medicine and Surgery
Lewis Katz School of Medicine at Temple University
Philadelphia, Pennsylvania
Chapter 84

Megan Rose Curtis, MD, MS
Research Fellow, Harvard Medical School
Associate Physician, Division of Infectious Diseases,
Brigham and Women's Hospital
Boston, Massachusetts
Chapter 122

AL GRAWANY

James B. Cutrell, MD
Associate Professor of Internal Medicine
Program Director, Infectious Diseases Fellowship Program
Director, Antimicrobial Stewardship, Clements University Hospital and UTSW Health Systems
Department of Internal Medicine
Division of Infectious Diseases and Geographic Medicine
University of Texas Southwestern Medical Center
Dallas, Texas
Chapter 136

Erin DeBiasi, MD
Assistant Professor of Medicine
Department of Internal Medicine
Section of Pulmonary,
Critical Care, and Sleep Medicine
Yale School of Medicine
New Haven, Connecticut
Chapters 47 and 64

Malcolm M. DeCamp, MD, FACS
Professor and Chair, Division of Cardiothoracic Surgery
University of Wisconsin Hospitals and Clinics
Madison, Wisconsin
Chapter 81

Roy H. Decker, MD, PhD
Professor, Department of Therapeutic Radiology
Yale School of Medicine
Radiation Oncologist
Yale New Haven Hospital
New Haven, Connecticut
Chapter 57

Marc Decramer, MD, PhD
Emeritus Professor of Medicine
University of Leuven
Laboratory of Respiratory Diseases and Thoracic Surgery (BREATHE)
Department of Chronic Diseases and Metabolism (CHROMETA), KU-Leuven
Leuven, Belgium
Chapter 3

Charles S. Dela Cruz, MD, PhD
Associate Professor of Medicine
Section of Pulmonary, Critical Care and Sleep Medicine
Associate Professor of Microbial Pathogenesis
Director, Center of Pulmonary Infection Research and Treatment
Yale School of Medicine
New Haven, Connecticut
Chapters 19 and 108

Horace M. DeLisser, MD
Associate Professor of Medicine
Department of Medicine
Associate Dean for Diversity and Inclusion
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapters 105 and 152

Bradley M. Dennis, MD
Associate Professor of Surgery
Division of Acute Care Surgery,
Vanderbilt University School of Medicine
Trauma Medical Director, Vanderbilt University Medical Center
Associate Chief of Staff, Vanderbilt University Hospital
Nashville, Tennessee
Chapter 104

Jessy Deshane, PhD
Associate Professor
Department of Medicine
Division of Pulmonary Allergy and Critical Care Medicine
University of Alabama at Birmingham
Birmingham, Alabama
Chapter 25

Himanshu Deshwal, MD
Fellow in Pulmonary Disease and Critical Care Medicine
Division of Pulmonary, Critical Care, and Sleep Medicine
New York University Grossman School of Medicine
New York, New York
Chapter 105

Joshua M. Diamond, MD, MSCE
Associate Professor of Medicine
Department of Medicine
Division of Pulmonary, Allergy and Critical Care Medicine
University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 121

David M. DiBardino, MD
Assistant Professor of Clinical Medicine
Section of Interventional Pulmonology
Division of Pulmonary, Allergy and Critical Care
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 33

Burton F. Dickey, MD
Clifton Howe Distinguished Professor of Pulmonary Medicine
University of Texas MD Anderson Cancer Center
Houston, Texas
Chapter 6

John D. Dickinson, MD, PhD
Assistant Professor of Medicine
Department of Internal Medicine
Division of Pulmonary, Critical Care, and Sleep Medicine
University of Nebraska Medical Center
Omaha, Nebraska
Chapter 6

Jennifer J. Dorsch, MD
Assistant Professor of Clinical Medicine
Perelman School of Medicine at the University of Pennsylvania
Division of Sleep Medicine,
The Hospital of the University of Pennsylvania
Associate Director, Sleep Non-Invasive Ventilation Program
Philadelphia, Pennsylvania
Chapter 142

Jonathan E. Dowell, MD
Professor of Internal Medicine
Division of Hematology/Oncology
UT Southwestern
Dallas, Texas
Chapter 116

Mark T. Dransfield, MD
Professor of Medicine, Endowed Chair in Pulmonary Disease
Division of Pulmonary, Allergy, and Critical Care Medicine
Lung Health Center
University of Alabama at Birmingham
Birmingham VA Medical Center
Birmingham, Alabama
Chapter 38

Benjamin J. Drapkin, MD, PhD
Assistant Professor of Internal Medicine
Division of Hematology/Oncology
UT Southwestern
Dallas, Texas
Chapter 116

M. Bradley Drummond, MD, MHS
Associate Professor of Medicine
Division of Pulmonary Diseases and Critical Care Medicine
University of North Carolina at Chapel Hill
Attending Physician
University of North Carolina at Chapel Hill Medical Center
Chapel Hill, North Carolina
Chapter 40

Hilary M. DuBrock, MD
Assistant Professor, Department of Internal Medicine
Mayo Clinic
Rochester, Minnesota
Chapter 97

Daniel G. Dunlap, MD
Assistant Professor of Medicine
Division of Pulmonary, Allergy, and Critical Care Medicine
University of Pittsburgh
Pittsburgh, Pennsylvania
Chapter 34

Ghassan El-Haddad, MD
Section Head, Radionuclide Therapy Program
Associate Member, Interventional Radiology
Associate Member, Cancer Physiology
H. Lee Moffitt Cancer Center and Research Institute
Associate Professor of Radiology and Oncologic Sciences
University of South Florida
Tampa, Florida
Chapter 30

Davide Elia, MD
Unità di Pneumologia e Terapia Semi-Intensiva Respiratoria
Servizio di Fisiopatologia Respiratoria ed Emodinamica Polmonare
Ospedale San Giuseppe, MultiMedica IRCCS
Milano, Italy
Chapter 59

Richard I. Enelow, MD
Professor of Medicine, and of Microbiology and Immunology
Geisel School of Medicine at Dartmouth
Dartmouth-Hitchcock Medical Center
Lebanon, New Hampshire
Chapter 56

Kyle B. Enfield, MD, MS
Associate Professor of Medicine
Section Chief, Critical Care
Department of Medicine
Division of Pulmonary and Critical Care Medicine
University of Virginia School of Medicine
Associate Chief Medical Officer for Critical Care UVA Health
Charlottesville, Virginia
Chapter 127

Perenlei Enkhbaatar, MD, PhD, FAHA
Professor, Department of Anesthesiology
Director, Translational Intensive Care Unit
Charles Robert Allen Professor in Anesthesiology
The University of Texas Medical Branch
Galveston, Texas
Chapter 93

Gary R. Epler, MD
Clinical Associate Professor
Harvard Medical School
Pulmonary and Critical Care Medicine
Brigham and Women's Hospital
Boston, Massachusetts
Chapter 49

Rodolfo A. Estrada, MD
Assistant Professor of Medicine
Division of Pulmonary and Critical Care
UT Health San Antonio/University of Texas Health Science
Center San Antonio
San Antonio, Texas
Chapter 79

Peter F. Fedullo, MD
Clinical Professor of Medicine
University of California San Diego Health
Division of Pulmonary, Critical Care, and Sleep Medicine
San Diego, California
Chapter 73

David Feller-Kopman, MD
Professor of Medicine, Department of Medicine, Geisel School of Medicine
Chief, Pulmonary and Critical Care Medicine,
Dartmouth Hitchcock Medical Center
Lebanon, New Hampshire
Chapter 76

Thomas W. Ferkol, MD
Alexis F. Hartmann M.D. Professor of Pediatrics
Department of Pediatrics
Professor, Department of Cell Biology and Physiology
Washington University School of Medicine
St. Louis Children's Hospital
St. Louis, Missouri
Chapter 6

Timothy M. Fernandes, MD, MPH
Associate Clinical Professor of Medicine
University of California, San Diego School of Medicine
Division of Pulmonary, Critical Care and Sleep Medicine
La Jolla, California
Chapter 73

Barry G. Fields, MD, MSEd
Associate Professor of Medicine
Division of Pulmonary, Allergy, Critical Care, and Sleep Medicine
Emory University School of Medicine
Sleep Physician, Sleep Medicine Center, Atlanta VA Health Care System
Atlanta, Georgia
Chapter 98

Michael C. Fishbein, MD
Distinguished Professor of Pathology and Medicine
Department of Pathology and Laboratory Medicine
David Geffen School of Medicine at UCLA
Ronald Reagan Medical Center
Los Angeles, California
Chapter 68

Christopher Gange, MD
Assistant Professor, Radiology and Biomedical Imaging
Yale University School of Medicine
Thoracic Radiologist
Yale New Haven Hospital
New Haven, Connecticut
Chapter 63

David E. Gerber, MD
David Bruton, Jr. Professorship in Clinical Cancer Research
Departments of Internal Medicine and Population and Data Sciences
Division of Hematology/Oncology
UT Southwestern
Dallas, Texas
Chapter 116

Ghislaine Gayan-Ramirez, PhD
Professor at University of Leuven
Laboratory of Respiratory Diseases and Thoracic Surgery (BREATHE)
Department of Chronic Diseases and Metabolism (CHROMETA),
KU-Leuven
Leuven, Belgium
Chapter 3

Subha Ghosh, MD, MBA
Assistant Professor, Lerner College of Medicine of Case
Western Reserve University
Staff Physician
Imaging Institute, Section of Thoracic Imaging
Cleveland Clinic Foundation
Cleveland, Ohio
Chapter 105

Timothy D. Girard, MD, MSCI, ATSF
Associate Professor of Critical Care Medicine
Department of Critical Care Medicine
University of Pittsburgh
Pittsburgh, Pennsylvania
Chapter 151

AL GRAWANY

Mark T. Gladwin, MD
Vice President for Medical Affairs, UM Baltimore
John Z. and Akiko K. Bowers Distinguished Professor and Dean, University of Maryland School of Medicine
Baltimore, Maryland
Chapter 95

Stanley Goldfarb, MD
Former Associate Dean for Curriculum
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 17

Michael A. Grippi, MD
Pulmonary, Allergy, and Critical Care Division
Department of Medicine
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapters 1, 10, 27, 31, 102, and 139

Marco Guazzi, MD, PhD
Professor of Cardiology,
University of Milano School of Medicine
Head of Cardiology Division
San Paolo University Hospital
Milano, Italy
Chapter 32

Mridu Gulati, MD, MPH
Associate Professor
Departments of Internal Medicine
Section of Pulmonary, Critical Care and Sleep Medicine
Yale School of Medicine
New Haven, Connecticut
Chapter 55

Akash Gupta, MD
Instructor, Harvard Medical School
Assistant in Medicine, Department of Medicine
Division of Infectious Diseases
Massachusetts General Hospital
Boston, Massachusetts
Chapter 130

Nishant Gupta, MD, MS
Associate Professor
Division of Pulmonary, Critical Care and Sleep Medicine
University of Cincinnati
Cincinnati, Ohio
Chapter 61

Indira Gurubhagavatula, MD, MPH, FAASM
Associate Professor of Medicine, Division of Sleep Medicine
Perelman School of Medicine at the University of Pennsylvania
Corporal Michael Crescenz VA Medical Center
Philadelphia, Pennsylvania
Chapter 100

Jacob Gutsche, MD
Associate Professor
Department of Anesthesiology and Critical Care
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 149

Duc M. Ha, MD, MAS
Assistant Professor of Medicine
Department of Medicine
University of Colorado Anschutz Medical Campus
Staff Physician, Section of Pulmonary and Critical Care
Rocky Mountain Regional Veterans Affairs Medical Center
Aurora, Colorado
Chapter 42

Andrew R. Haas, MD, PhD
Associate Professor of Medicine
Director, Section of Interventional Pulmonary and Thoracic Oncology
Pulmonary, Allergy, and Critical Care Division
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 34

Ramsey R. Hachem, MD
Professor of Medicine
Division of Pulmonary and Critical Care Medicine
Department of Medicine
Washington University in St. Louis
Medical Director of Lung Transplantation
Barnes-Jewish Hospital
St. Louis, Missouri
Chapter 106

Chadi A. Hage, MD, ATSF
Professor of Medicine
University of Pittsburgh
Pulmonary, Allergy, and Critical Care Medicine
McGowan Institute for Regenerative Medicine
Medical Director, Lung Transplant
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania
Chapter 133

Kelly M. Hager, MD, MPH
Fellow, Yale Occupational and Environmental Medicine
Department of Medicine, Yale University School of Medicine
New Haven, Connecticut
Chapter 55

Stephen R. Hammes, MD, PhD
Professor and Chief, Division of Endocrinology
Department of Medicine
University of Rochester School of Medicine and Dentistry
Rochester, New York
Chapter 62

Sergio Harari, MD
Professor of Internal Medicine
University of Milan
Unità di Pneumologia e Terapia Semi-Intensiva Respiratoria
Servizio di Fisiopatologia Respiratoria ed Emodinamica Polmonare
Ospedale San Giuseppe, MultiMedica IRCCS
Department of Medical Sciences, San Giuseppe Hospital
MultiMedica IRCCS
Department of Clinical Sciences and Community Health
Università degli Studi di Milano
Milan, Italy
Chapter 59

Howard M. Heller, MD, MPH
Assistant Professor of Medicine, Harvard Medical School
Infectious Disease Division, Massachusetts General Hospital
Boston, Massachusetts
Chapter 138

Michael J. Herriges, PhD
Post-doctoral Fellow
Center for Regenerative Medicine (CReM) of Boston
University and Boston Medical Center
Boston, Massachusetts
Chapter 8

Søren Hess, MD
Chief Physician, Head of Section (Nuclear Medicine & PET)
Department of Radiology and Nuclear Medicine
Hospital South West Jutland
Esbjerg, Denmark
Clinical Associate Professor, Head of Research (Imaging)
Research Unit for Radiology and Nuclear Medicine
Department of Regional Health Research, Faculty of Health Sciences
University of Southern Denmark
Odense, Denmark
Chair, Danish Society of Clinical Physiology and Nuclear Medicine
Aarup, Denmark
Chapter 30

Janet Hilbert, MD
Associate Professor of Clinical Medicine
Medical Director of Yale Noninvasive Ventilation Program
Division of Pulmonary and Critical Care Medicine
Yale University
New Haven, Connecticut
Chapter 148

Robert J. Homer, MD, PhD
Professor of Pathology
Yale University School of Medicine
New Haven, Connecticut
Chapter 63

Gary B. Huffnagle
Department of Internal Medicine
Department of Molecular Cell and Developmental Biology
Division of Pulmonary and Critical Care Medicine
University of Michigan Medical Center
Ann Arbor, Michigan
Chapter 120

Rocio M. Hurtado, MD
Assistant Professor of Medicine, Harvard Medical School
Director, Mycobacterial Center, Division of Infectious Diseases
Massachusetts General Hospital
Boston, Massachusetts
Chapter 131

Louise C. Ivers, MD, MPH
Professor of Medicine, Professor of Global Health and Social Medicine, Harvard Medical School
Director, Center for Global Health, Massachusetts General Hospital
Boston, Massachusetts
Chapter 135

Karen R. Jacobson, MD, MPH
Associate Professor of Medicine
Section of Infectious Diseases
Boston University School of Medicine and Boston Medical Center
Boston, Massachusetts
Chapter 130

Frank J. Jacono, MD
Virginia Hubbell Chair in Pulmonary and Critical Care and Tenured Professor of Medicine
Case Western Reserve University School of Medicine
Division Chief, Pulmonary, Critical Care & Sleep Medicine
University Hospitals Cleveland Medical Center
Cleveland VA Medical Center, VA Northeast Ohio Health System
Cleveland, Ohio
Chapter 11

Tulip Ajit Jhaveri, MBBS
Assistant Professor of Medicine, University of Mississippi School of Medicine
Attending Physician, Division of Infectious Diseases, University of Mississippi Medical Center
Jackson, Mississippi
Chapter 122

David H. Johnson, MD
R. Ellwood Jones, M.D. Distinguished Professorship in Clinical Education
Department of Internal Medicine
Division of Hematology/Oncology
UT Southwestern
Dallas, Texas
Chapter 116

Austin J. Jolly
MD/PhD Student, Department of Medicine
University of Colorado Anschutz Medical Campus
Aurora, Colorado
Chapter 90

Christopher M. Kapp, MD
Clinical Instructor of Medicine, Department of Medicine,
University of Illinois at Chicago College of Medicine
Interventional Pulmonologist and Pulmonary Critical Care Medicine Physician, Department of Medicine, University of Illinois Hospital
Chicago, Illinois
Chapter 76

Joel D. Kaufman, MD, MPH
Professor
Departments of Environmental & Occupational Health Sciences
University of Washington
Medicine, and Epidemiology
Seattle, Washington
Chapter 89

Joshua B. Kayser, MD, MPH, MBE, FCCM
Professor of Clinical Medicine and Medical Ethics & Health Policy
Department of Medicine
Department of Medical Ethics & Health Policy
Perelman School of Medicine University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 152

Michael P. Keane, MD, FRCP, FRCPI
Professor of Medicine
Dean and Head of School of Medicine
University College Dublin
Consultant Respiratory Physician
St. Vincent's University Hospital
Dublin, Ireland
Chapter 24

Andrea Kelly, MD MSCE
Attending Physician, Division of Endocrinology and Diabetes
Children's Hospital of Philadelphia
Professor of Pediatrics
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 48

Jeffrey A. Kern, MD
Professor of Medicine
National Jewish Health
University of Colorado, Denver
Chief, Oncology Division
Vice-Chair, Department of Medicine
National Jewish Health
Denver, Colorado
Chapter 107

Nick H. Kim, MD
Professor of Medicine
Section Chief, Pulmonary Vascular Medicine
Medical Director, Pulmonary Thromboendarterectomy Program
Pulmonary, Critical Care, and Sleep Medicine
University of California San Diego
La Jolla, California
Chapter 72

Corrine R. Kliment, MD, PhD
Assistant Professor
Department of Medicine
Division of Pulmonary, Allergy and Critical Care Medicine
University of Pittsburgh
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania
Chapter 18

Robert A. Klocke, MD
Emeritus Professor of Chairperson
Department of Medicine
Jacobs School of Medicine and Biomedical Sciences
University at Buffalo
Buffalo, New York
Chapters 15 and 16

Marin H. Kollef, MD
Director, Critical Care Research
Director, Respiratory Care Services Barnes-Jewish Hospital
Virginia E. and Sam J. Golman Chair in Respiratory Intensive Care Medicine
Professor of Medicine
Division of Pulmonary and Critical Care Medicine
Washington University School of Medicine
St. Louis, Missouri
Chapter 129

AL GRAWANY

Dimitrios P. Kontoyiannis, MD, ScD, FACP, FIDSA
Frances King Black Endowed Professor, Infectious Diseases
Deputy Head
Division of Internal Medicine
The University of Texas MD Anderson Cancer Center
Adj Professor Baylor College of Medicine
Adj Professor University of Houston
Houston, Texas
Chapter 132

Robert M. Kotloff, MD
Craig and Elaine Dobbin/Nancy P. Blumenthal
Professor of Advanced Lung Disease
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapters 94 and 103

Darrell N. Kotton, MD
David C. Seldin Professor of Medicine
The Pulmonary Center and Department of Medicine
Boston University School of Medicine
Director, Center for Regenerative Medicine (CReM) of Boston
University and Boston Medical Center
Attending Physician
Department of Medicine
Boston Medical Center
Boston, Massachusetts
Chapters 8 and 39

Mary Elizabeth Kreider, MD, MSCE
Professor of Clinical Medicine
Vice Chief for Education and Faculty Development
Fellowship Program Director
Director, ILD Program
Division of Pulmonary and Critical Care Medicine
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 86

Arnold S. Kristof, MDCM, FRCPC
Associate Professor of Medicine
Meakins-Christie Laboratories and Translational Research in Respiratory
Diseases Program
Research Institute of the McGill University Health Centre
Departments of Critical Care and Medicine, McGill University
Montreal, Quebec
Chapter 60

Meir Kryger, MD, FRCPC
Professor, Pulmonary, Critical Care, and Sleep Medicine
Yale School of Medicine
New Haven, Connecticut
Chapters 47 and 101

Ricardo M. La Hoz, MD
Director, Solid Organ Transplant Infectious Diseases
Associate Professor of Internal Medicine
Department of Internal Medicine
Division of Infectious Diseases and Geographic Medicine
University of Texas Southwestern Medical Center
Dallas, Texas
Chapter 136

James H. Laird, MD
Resident Physician
Department of Therapeutic Radiology
Yale School of Medicine
Resident Physician
Yale New Haven Hospital
New Haven, Connecticut
Chapter 57

Daniel Langer, PT, PhD
Professor of Rehabilitation Sciences and Physiotherapy
Department of Rehabilitation Sciences
Research Group for Cardiovascular and Respiratory Rehabilitation
KU-Leuven
Respiratory Rehabilitation and Respiratory Division
University Hospital Leuven
Leuven, Belgium
Chapter 3

Kathleen A. Lee-Sarwar, MD, MS
Instructor, Harvard Medical School
Physician, Department of Medicine, Brigham and Women's Hospital
Boston, Massachusetts
Chapter 44

Andrew T. Levinson, MD, MPH
Associate Professor of Medicine, Clinician Educator
Program Director, Critical Care Medicine Fellowship
Warren Alpert Medical School of Brown University
Department of Medicine
Miriam Hospital and Rhode Island Hospital
Providence, Rhode Island
Chapter 96

Erik E. Lewis, MD
Fellow, Division of Cardiothoracic Surgery, University of Wisconsin
Hospitals and Clinics
Madison, Wisconsin
Chapter 81

Howard Y. Li, MD
Associate Professor
Department of Internal Medicine
Division of Pulmonary Disease and Critical Care Medicine
Virginia Commonwealth University
Director, Lung Cancer Screening
Medical Service
Section of Pulmonary and Critical Care Medicine
Hunter Holmes McGuire Veterans Affairs Medical Center
Richmond, Virginia
Chapter 107

Shu-Yi Liao, MD, MPH, MS, ScD
Assistant Professor of Medicine
Department of Medicine
National Jewish Health
Assistant Professor of Medicine
Department of Medicine
University of Colorado Anschutz Medical Campus
Physician
Department of Medicine
Division of Environmental & Occupational Health Sciences
National Jewish Health
Denver, Colorado
Chapter 88

Augusto A. Litonjua, MD, MPH
Professor of Pediatrics and Medicine
Department of Pediatrics and Department of Medicine
University of Rochester School of Medicine and Dentistry
Division Chief of Pediatric Pulmonary Medicine
Physician, Department of Pediatrics, Golisano Children's Hospital
Department of Medicine, Strong Memorial Hospital, University of
Rochester Medical Center
Rochester, New York
Chapter 44

Leslie A. Litzky, MD
Professor, Pathology and Laboratory Medicine
Perelman School of Medicine at the University of Pennsylvania
Chief of Surgical and Medical Pathology
Subspecialty Director, Thoracic Pathology
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania
Chapters 78 and 111

Jining Lu, PhD
Program Director
Division of Lung Diseases
National Heart, Lung, and Blood Institute
National Institutes of Health
Bethesda, Maryland
Chapter 4

Natalie S. Lui, MD
Assistant Professor of Cardiothoracic Surgery
Stanford University School of Medicine/Stanford Cancer Institute
Stanford, California
Chapter 82

Joseph P. Lynch, III, MD, FCCP, FERS
Holt and Jo Hickman Endowed Chair of Advanced Lung Disease and Lung Transplantation
Distinguished Professor of Clinical Medicine
Division of Pulmonary and Critical Care Medicine,
Clinical Immunology, and Allergy
David Geffen School of Medicine at UCLA
Los Angeles, California
Chapter 68

Kevin C. Ma, MD
Assistant Professor of Clinical Medicine
Section of Interventional Pulmonology and Thoracic Oncology
Division of Pulmonary, Allergy, and Critical Care
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 77

Roberto F. Machado, MD
Dr. Calvin H. English Professor of Medicine
Chief, Division of Pulmonary, Critical Care, Sleep, and Occupational Medicine
Department of Medicine
Indiana University
Indianapolis, Indiana
Chapter 95

Mitchell Machtay, MD
Professor of Radiation Oncology
Department of Radiation Oncology
Penn State University College of Medicine and Cancer Institute
Hershey, Pennsylvania
Chapter 115

Atul Malhotra, MD
Peter C. Farrell Presidential Chair and Tenured Professor of Medicine
University of California San Diego
Division of Pulmonary, Critical Care & Sleep Medicine
La Jolla, California
Chapter 10

Joshua Malo, MD
Associate Professor of Medicine, Clinical Scholar
Associate Director, Internal Medicine Residency Program—Tucson Campus
Tucson, Arizona
Chapter 133

Scott Manaker, MD, PhD
Professor of Medicine
University of Pennsylvania
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 144

Jess Mandel, MD, MACP, ATSF
Kenneth M. Moser Professor of Medicine
Chief, Division of Pulmonary, Critical Care, and Sleep Medicine
Vice-Chair for Education, Department of Internal Medicine
UC San Diego School of Medicine
La Jolla, California
Chapter 72

Keshav Mangalick, MD
Resident Physician, Department of Medicine
New York University Grossman School of Medicine
Resident Physician, Department of Medicine
New York University Langone Health
New York, New York
Chapter 78

Patrick Mangialardi, DO
Senior Fellow, Pulmonary, Critical Care and Sleep Medicine
Department of Internal Medicine
Division of Pulmonary, Critical Care and Sleep Medicine
University of California, Davis, Sacramento
Veterans Administration Northern California Health Care System
Department of Medicine
Mather, California
Chapter 66

Nathaniel Marchetti, DO
Professor of Thoracic Medicine and Surgery
Department of Thoracic Medicine and Surgery
Lewis Katz School of Medicine at Temple University
Philadelphia, Pennsylvania
Chapter 84

Paul E. Marik, MD, FCCP, FCCM
Professor, Pulmonary and Critical Care Medicine
Department of Internal Medicine
Eastern Virginia Medical School
Norfolk, Virginia
Chapter 69

Fernando J. Martinez, MD, MS
Chief, Division of Pulmonary and Critical Care Medine
Joan and Sanford Weill Department of Medicine
Weill Cornell Medicine
NY Presbyterian Hospital
New York, New York
Chapter 50

Fiore Mastroianni, MD
Attending Intensivist and Pulmonologist
Department of Intensive Care and Pulmonary Medicine
Mather Hospital
Northwell Health
Port Jefferson, New York
Chapter 29

Aditi Mathur, MD
Attending Pulmonary Physician
Summit Health, Department of Pulmonary, Critical Care & Sleep Medicine
Hackensack University Medical Center
Montclair, New Jersey
Chapter 52

Michael A. Matthay, MD
Professor, Departments of Medicine and Anesthesia
Senior Associate Cardiovascular Research Institute
University of California San Francisco
Associate Director, Critical Care Medicine
University of California, San Francisco Medical Center
San Francisco, California
Chapter 140

Daniel N. Maxwell, MD
Fellow of Infectious Disease and Critical Care, UT Southwestern
Fellow of Infectious Disease and Critical Care
Parkland Hospital, Clements Hospital, North Texas VA Hospital
Dallas, Texas
Chapter 137

Paul H. Mayo, MD, FAACP
Professor of Clinical Medicine at the Donald and Barbara Zucker School of Medicine at Hofstra/Northwell
Academic Director of Critical Care
Division of Pulmonary, Critical Care, and Sleep Medicine
Department of Medicine
Northwell Health
New Hyde Park, New York
Chapter 29

Jeffrey Mazer, MD
Director of Pulmonary and Critical Care
Lovelace Medical Group
Albuquerque, New Mexico
Chapter 96

Peter J. Mazzone, MD, MPH
Section Head, Thoracic Oncology
Respiratory Institute
Cleveland Clinic
Cleveland, Ohio
Chapter 109

Cormac McCarthy, MD, PhD
Associate Professor of Medicine
School of Medicine, University College Dublin
Consultant Respiratory Physician, St. Vincent's University Hospital
Dublin, Ireland
Chapter 70

Daniel P. McCarthy, MD, MBA, MEM
Assistant Professor, Division of Cardiothoracic Surgery
University of Wisconsin Hospitals and Clinics
Madison, Wisconsin
Chapter 81

F. Dennis McCool, MD
Professor of Medicine, Warren Alpert Medical School of Brown University
Division of Pulmonary Critical Care and Sleep Medicine
Rhode Island Hospital
Providence, Rhode Island
Chapter 83

John E. McGinniss, MD
Assistant Professor of Medicine
Department of Medicine
Division of Pulmonary, Allergy, and Critical Care Medicine
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 121

Paul McLoughlin, MB, BCh, MRCPI, PhD
Professor of Physiology
University College Dublin
School of Medicine
Conway Institute of Biomedical and Biomolecular Research
St. Vincent's University Hospital
Dublin, Ireland
Chapter 24

Robert E. Merritt, MD, FACS
Professor of Surgery
Director, Division of Thoracic Surgery
Medical Director of Inpatient Services
The James Comprehensive Cancer Center
The Ohio State University Wexner Medical Center
Columbus, Ohio
Chapter 35

Joseph A. Miccio, MD
Assistant Professor of Radiation Oncology
Department of Radiation Oncology
Penn State University College of Medicine and Cancer Institute
Hershey, Pennsylvania
Chapter 115

Joseph P. Mizgerd, ScD
Jerome S. Brody, MD, Professor of Pulmonary Medicine
Professor of Medicine, Microbiology, and Biochemistry
Director, Pulmonary Center
Pulmonary Center, Boston University School of Medicine
Boston, Massachusetts
Chapter 20

Takudzwa Mkorombindo, MD
Division of Pulmonary, Allergy, and Critical Care Medicine
Lung Health Center
University of Alabama at Birmingham
Birmingham VA Medical Center
Birmingham, Alabama
Chapter 38

Edmund K. Moon, MD
Medical Director
Cell & Gene Therapy
Oncology R&D
Collegeville, Pennsylvania
Chapter 78

Richard E. Moon, MD, FACP, FCCP
Professor of Anesthesiology
Professor of Medicine
Duke University Medical Center
Durham, North Carolina
Chapter 92

Jorge I. Mora, MD
Associate Professor of Clinical Medicine
Perelman School of Medicine at the University of Pennsylvania
Associate Chief for Clinical Affairs and
Medical Director Division of Sleep Medicine
Hospital of the University of Pennsylvania
Director, Sleep Non-Invasive Ventilation Program
Philadelphia, Pennsylvania
Chapter 99

Alice Moroni, MD
Resident in Cardiology
University of Milano school of Medicine
Milano, Italy
Chapter 32

Joel Moss, MD, PhD
Senior Investigator, Pulmonary Branch
National Heart, Lung, and Blood Institute, National Institutes of Health
Clinical Center, National Institutes of Health
Bethesda, Maryland
Chapters 59, 60, and 62

Prerna Mota, MD
Assistant Professor of Medicine
Geisel School of Medicine at Dartmouth
Dartmouth-Hitchcock Medical Center
Lebanon, New Hampshire
Chapter 56

Susan Murin, MD, MBA
Professor and Associate Dean
Department of Internal Medicine
Division of Pulmonary, Critical Care and Sleep Medicine
University of California
Davis, Sacramento
Department of Medicine
Veterans Administration Northern California Health Care System
Mather, California
Chapter 66

Robert Naeije, MD, PhD
Professor of Physiology
Department of Physiology
Erasme Campus of the Free University of Brussels
Brussels, Belgium
Chapter 13

Girish B. Nair, MD, MS, FACP, FCCP
Division of Pulmonary and Critical Care
Beaumont Health
Associate Professor of Medicine
OUWB School of Medicine
Royal Oak, Michigan
Chapter 125

Camille Nelson Kotton, MD
Associate Professor, Harvard Medical School
Clinical Director, Transplant and Immunocompromised Host
Infectious Diseases
Infectious Diseases Division, Massachusetts General Hospital
Boston, Massachusetts
Chapters 123 and 138

Natalia Neparidze, MD
Associate Professor
Research DART Leader, Multiple Myeloma and Gammopathies Program
Section of Hematology
Department of Internal Medicine and Yale Cancer Center
Yale University School of Medicine
New Haven, Connecticut
Chapter 63

Nikolaus C. Netzer, MD, PhD
Prof. Prof.(Hon)/Director Hermann Buhl Institute for Hypoxia and Sleep Medicine Research
University Innsbruck
Innsbruck, Austria
Scientific Medical Director, Terra X Cube
Institute of Mountain Emergency Medicine
Eurac Research
Bozen, Italy
Chapter 91

Michael S. Niederman, MD, MACP, FCCP, FCCM, FERS
Professor of Clinical Medicine
Division of Pulmonary and Critical Care Medicine
New York Presbyterian/Weill Cornell Medical Center
Weill Cornell Medical College
New York, New York
Chapter 125

Paul W. Noble, MD
Professor of Medicine and Chair, Department of Medicine
Vera and Paul Guerin Family Distinguished Chair in Pulmonary Medicine
Medical Director, Women's Guild Lung Institute
Cedars-Sinai Medical Center
Los Angeles, California
Chapter 54

Eliezer Zachary Nussbaum
Fellow in infectious diseases
Department of infectious disease
Massachusetts General Hospital
Boston, Massachusetts
Chapter 134

Matthias Ochs, MD
Professor and Chair, Institute of Functional Anatomy, Charité—Universitätsmedizin Berlin, Germany
Chapter 2

Philip G. Ong, MD
Associate Professor of Medicine, Division of Pulmonary and Critical Care
UT Health San Antonio/University of Texas Health Science Center San Antonio
San Antonio, Texas
Chapter 79

David E. Ost, MD, MPH
Professor of Medicine, Department of Pulmonary Medicine
The University of Texas MD Anderson Cancer Center
Houston, Texas
Chapter 110

Gustavo Pacheco-Rodriguez, PhD
Staff Scientist, Pulmonary Branch
National Heart, Lung, and Blood Institute
National Institutes of Health
Bethesda, Maryland
Chapter 62

Allan I. Pack, MBChB, PhD
John Miclot Professor of Medicine
Division of Sleep Medicine
Department of Medicine
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapters 10 and 12

Henry S. Park, MD, MPH
Assistant Professor, Department of Therapeutic Radiology
Yale School of Medicine
Radiation Oncologist
Yale New Haven Hospital
New Haven, Connecticut
Chapter 57

John E. Parker, MD
Professor of Pulmonary Critical Care and Sleep Medicine
Department of Medicine
West Virginia University
Morgantown, West Virginia
Chapter 87

Nicholas J. Pastis, MD
Professor of Medicine
Director of Interventional Pulmonology
Interventional Pulmonology Fellowship Program Director
The Ohio State University Wexner Medical Center
Columbus, Ohio
Chapter 118

Susheel P. Patil, MD, PhD
Clinical Associate Professor of Medicine
Pulmonary, Critical Care, and Sleep Medicine
University Hospitals Cleveland Medical Center
Cleveland, Ohio
Chapter 100

Tyler J. Peck, MD
Instructor of Medicine, Harvard Medical School
Physician, Division of Pulmonary, Critical Care, and Sleep Medicine
Beth Israel Deaconess Medical Center
Boston, Massachusetts
Chapter 75

Jay I. Peters, MD
Professor of Medicine, Division of Pulmonary and Critical Care
UT Health San Antonio/University of Texas Health Science Center San Antonio and the South Texas Veterans Health Care System
San Antonio, Texas
Chapter 79

Steve G. Peters, MD
Professor of Medicine
Division of Pulmonary/Critical Care Medicine
Mayo Clinic
Rochester, Minnesota
Chapter 94

Sara Piciucchi, MD
Team Leader of Thoracic Radiology and Consultant
Department of Radiology
Ospedale GB Morgagni
Forlì, Italy
Chapter 119

Grace W. Pien, MD, MSCE
Program Director, Sleep Medicine Fellowship Program
Assistant Professor of Medicine
Pulmonary and Critical Care Division
Johns Hopkins School of Medicine
Baltimore, Maryland
Chapter 98

Gerald B. Pier, PhD
Professor of Medicine (Microbiology and Immunology)
Department of Medicine, Harvard Medical School
Senior Investigator, Department of Medicine
Brigham and Women's Hospital
Boston, Massachusetts
Chapter 124

Venerino Poletti, MD
Professor of Pulmonary Medicine, Dipartimento di Medicina Specialistica e Sperimentale (DIMES)
Università di Bologna
Bologna, Italy
Honorary Professor of Pulmonary Medicine
Department of Clinical Medicine
Aarhus University Hospital
Aarhus, Denmark
Head & Professor, Department of Pulmonology, Ospedale GB Morgagni
Forlì, Italy
Chapter 119

Jennifer D. Possick, MD
Associate Professor of Medicine
Department of Internal Medicine
Section of Pulmonary,
Critical Care, and Sleep Medicine
Yale School of Medicine
Director, Winchester Center for Lung Disease
Yale-New Haven Hospital
New Haven, Connecticut
Chapter 64

Niall T. Prendergast, MD
Research Fellow, Division of Pulmonary,
Allergy, and Critical Care Medicine
Attending Physician, Department of Medicine
University of Pittsburgh Medical Center
University of Pittsburgh
Pittsburgh, Pennsylvania
Chapter 151

Gregory P. Priebe, MD
Associate Professor of Anaesthesia, Harvard Medical School
Senior Associate in Critical Care Medicine
Department of Anesthesiology, Critical Care and Pain Medicine
Associate in Pediatrics
Department of Pediatrics, Division of Infectious Diseases
Boston Children's Hospital
Boston, Massachusetts
Chapter 124

Benjamin A. Raby, MD, CM, MPH
Professor of Pediatrics
Division of Pulmonary Medicine
Boston Children's Hospital
Harvard Medical School
Boston, Massachusetts
Chapter 9

Christopher H. Rassekh, MD, FACS
Professor of Clinical Otorhinolaryngology: Head and Neck Surgery
Department of Otorhinolaryngology: Head and Neck Surgery
Perelman School of Medicine at the University of Pennsylvania
Attending Physician, Co-Chair Airway Safety Committee
Director of Risk Reduction, Professional Practice, and
Salivary Gland Center
Department of Otorhinolaryngology: Head and Neck Surgery
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 145

John P. Reilly, MD, MSCE
Assistant Professor of Medicine
Division of Pulmonary, Allergy, and Critical Care
Department of Medicine
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 141

Stephen I. Rennard, MD
Internal Medicine, Division of Pulmonary, Critical Care, Sleep & Allergy
University of Nebraska Medical Center
Omaha, Nebraska
Chapter 41

Alejandro Restrepo, MD
Clinical Assistant Professor
Department of Medicine
UTMB Health
League City, Texas
Chapter 137

Scott I. Reznik, MD
Associate Professor
Department of Cardiovascular and Thoracic Surgery
University of Texas Southwestern Medical Center
Dallas, Texas
Chapter 113

Andrew L. Ries, MD, MPH
Professor of Medicine and Public Health
Associate Vice Chancellor for Health Sciences Academic Affairs
University of California, San Diego
San Diego, California
Chapter 42

M. Patricia Rivera, MD
C. Jane Davis & C. Robert Davis Distinguished
Professor in Pulmonary Medicine
Chief, Division of Pulmonary and Critical Care Medicine
University of Rochester
Associate Director of DEI, Wilmot Cancer Center
University of Rochester Medical Center
Rochester, New York
Chapter 112

Kenneth B. Roberts, MD
Professor, Department of Therapeutic Radiology
Yale University School of Medicine
Attending Physician, Department of Radiation Oncology
Yale-New Haven Health System
New Haven, Connecticut
Chapter 57

Matthew B. Roberts, MBBS, MPH&TM, FRACP
Infectious Diseases Physician, Infectious Diseases Unit
Royal Adelaide Hospital
Adelaide, South Australia
Chapter 123

Carolyn L. Rochester, MD
Professor, Section of Pulmonary, Critical Care and Sleep Medicine
Yale School of Medicine
New Haven, Connecticut
VA Connecticut Healthcare System
West Haven, Connecticut
Chapter 71

Karen Rodriguez, MD
Department of Radiology
Division of Thoracic Imaging & Intervention
Massachusetts General Hospital
Instructor, Harvard Medical School
Boston, Massachusetts
Chapter 117

Josanna M. Rodriguez-Lopez, MD
Instructor of Medicine, Harvard Medical School
Physician, Division of Pulmonary and Critical Care Medicine
Massachusetts General Hospital
Boston, Massachusetts
Chapter 75

William N. Rom, MD, MPH
Sol and Judith Bergstein Professor, Emeritus
Department of Medicine
Division of Pulmonary, Critical Care, and Sleep Medicine
NYU Grossman School of Medicine
Research Scientist
NYU School of Global Public Health
New York, New York
Chapter 85

AL GRAWANY

Ilene M. Rosen, MD, MSCE
Assistant Dean for Graduate Medical Education
Vice Chair for Education, Department of Medicine
Associate Professor of Medicine
Division of Sleep Medicine
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 98

Leonid Roshkovan, MD
Department of Radiology
Hospital of the University of Pennsylvania
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 28

Andrew T. Roth, MD
Fellow
Department of Medicine
Division of Pulmonary and Critical Care Medicine
Washington University School of Medicine
St. Louis, Missouri
Chapter 129

Ami Rubinowitz, MD
Associate Professor of Radiology & Biomedical Imaging
Yale School of Medicine
Thoracic Imaging Section
Yale-New Haven Hospital
New Haven, Connecticut
Chapter 55

Lisa Ruvuna, MD
Fellow, Division of Pulmonary Sciences and Critical Care Medicine
University of Colorado Anschutz Medical Campus
University of Colorado School of Medicine
Denver, Colorado
Chapter 36

Edward T. Ryan, MD
Professor of Medicine, Harvard Medical School
Professor of Immunology and Infectious Diseases
Harvard T.H. Chan School of Public Health
Director, Global Infectious Diseases, Massachusetts General Hospital
Boston, Massachusetts
Chapter 135

Coralynn Sack, MD, MPH
Assistant Professor
Departments of Medicine and Environmental &
Occupational Health Sciences
University of Washington
Seattle, Washington
Chapter 89

Moiz Salahuddin, MD
Interventional Pulmonary fellow, Interventional Pulmonology
MD Anderson Cancer Center
Houston, Texas
Chapter 110

Amali E. Samarasinghe, MS, PhD
Plough Foundation Endowed Chair of Excellence
Director of the Pediatric Asthma Research Center
Associate Professor, Department of Pediatrics, Division of Pulmonology
University of Tennessee Health Science Center
Le Bonheur Children's Hospital
Children's Foundation Research Institute
Memphis, Tennessee
Chapter 21

Rahul G. Sangani, MD
Associate Professor, Section of Pulmonary, Critical Care and Sleep Medicine
West Virginia University Department of Medicine
Morgantown, West Virginia
Chapter 87

Thomas F. Scanlin, MD
Chief, Division of Pediatric Pulmonary Medicine and
The Cystic Fibrosis Center
Professor, Department of Pediatrics,
Rutgers, Robert Wood Johnson Medical School
New Brunswick, New Jersey
Chapter 48

Edward S. Schulman, MD
Professor of Medicine
Division of Pulmonary, Critical Care and Sleep Medicine
Director, Allergy and Asthma Research Center
Drexel University College of Medicine
Philadelphia, Pennsylvania
Chapter 21

Richard J. Schwab, MD
Professor of Medicine
Perelman School of Medicine at the University of Pennsylvania
Chief, Division of Sleep Medicine
The Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 99

David A. Schwartz, MD
Distinguished Professor of Medicine and Immunology
Anschutz Medical Campus
University of Colorado Denver
Aurora, Colorado
Chapter 90

Bernardo Selim, MD
Associate Professor of Medicine
Medical Director of Respiratory Care Unit
Division of Pulmonary and Critical Care Medicine
Mayo Clinic
Rochester, Minnesota
Chapter 148

Mithu Sen, MD, FRCPC, DABSM, ABIM, FCCP, FCCM, FAASM
Professor of Medicine, University of Western Ontario
Schulich School of Medicine & Dentistry
Department of Medicine
Division of Respirology, Critical Care, & Sleep Medicine
London, Canada
Chapter 101

David S. Seres, MD
Professor of Medicine in the Institute of Human Nutrition
Director of Medical Nutrition
Associate Clinical Ethicist
Department of Medicine
Columbia University Irving Medical Center
New York, New York
Chapter 150

Hari M. Shankar, MD
Assistant Professor of Clinical Medicine
Department of Medicine
Division of Pulmonary, Allergy & Critical Care Medicine
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 146

Adrian Shifren, MBBCh, FCCP
Associate Professor of Medicine
Washington University School of Medicine
St. Louis, Missouri
Chapters 15 and 16

Joseph B. Shrager, MD
Professor of Cardiothoracic Surgery
Chief, Division of Thoracic Surgery
Director, Thoracic Oncology CCP
Stanford University School of Medicine/Stanford Cancer Institute
Stanford, California
Chapter 82

Costi D. Sifri, MD
Becton, Dickinson and Company Endowed Chair of Infectious Diseases and International Health Division of Infectious Diseases and International Health Department of Medicine, University of Virginia School of Medicine
Attending Physician and Director, Hospital Epidemiology/Infection Prevention & Control UVA Health
Charlottesville, Virginia
Chapter 127

Gerard A. Silvestri, MD, MS
Hillenbrand Professor of Thoracic Oncology
Senior Vice-Chair of Faculty Development
Department of Medicine
Medical University of South Carolina
Charleston, South Carolina
Chapter 118

Kimberly A. Smith, PhD
Research Associate
Department of Pediatrics
Northwestern University
Chicago, Illinois
Chapter 72

Nilam J. Soni, MD
Professor of Medicine, Academic Hospitalist
UT Health San Antonio/University of Texas Health Science Center San Antonio and the South Texas Veterans Health Care System
San Antonio, Texas
Chapter 79

Akshay Sood, MD, MPH
Professor, Department of Internal Medicine
University of New Mexico School of Medicine
Albuquerque, New Mexico
Chapter 36

Shweta Sood, MD, MS
Assistant Professor of Clinical Medicine
Medical Director of Perelman Harron Lung Center
Division of Pulmonary and Critical Care Medicine
The Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 86

Ulrich Specks, MD
Professor of Medicine, Mayo Clinic College of Medicine and Science
Consultant, Department of Medicine
Division of Pulmonary and Critical Care Medicine
Mayo Clinic
Rochester, Minnesota
Chapter 74

Peter H.S. Sporn, MD
Professor of Medicine
Cell and Developmental Biology, and Medical Education
Northwestern University Feinberg School of Medicine
Chicago, Illinois
Chapter 21

Theodore J. Standiford, MD
Professor of Medicine
Chief, Division of Pulmonary and Critical Care Medicine
University of Michigan Medical Center
Ann Arbor, Michigan
Chapter 120

Robert C. Stansbury, MD
Associate Professor
Department of Medicine
Section of Pulmonary, Critical Care and Sleep Medicine
West Virginia University
Morgantown, West Virginia
Chapter 87

Daniel H. Sterman, MD, FCCP, ATSF, DAABIP
Thomas & Suzanne Murphy Professor of Pulmonary & Critical Care Medicine
Departments of Medicine and Cardiothoracic Surgery
Director, Division of Pulmonary, Critical Care & Sleep Medicine
Director, Multidisciplinary Pulmonary Oncology Program
Principal Investigator, NYU Pulmonary Oncology Research Team (NYU PORT)
NYU Grossman School of Medicine/NYU Langone Health
New York, New York
Chapters 33, 34, and 78

Kingman P. Strohl, MD
Professor, Medicine and Physiology & Biophysics
Case Western Reserve University
Cleveland, Ohio
Chapter 91

Erik R. Swenson, MD
Professor of Medicine and Physiology
Division of Pulmonary, Critical Care and Sleep Medicine
University of Washington School of Medicine
Attending Physician
Pulmonary, Critical Care and Sleep Medicine
VA Puget Sound Health Care System
Seattle, Washington
Chapter 143

Flora K. Szabo, MD, PhD
Assistant Professor of Pediatrics
Department of Pediatrics
Division of Gastroenterology, Hepatology and Nutrition
Children's Hospital of Richmond, VCU
Richmond, Virginia
Chapter 48

Nichole T. Tanner, MD, MSCR
Professor of Medicine
Co-Director, Hollings Lung Cancer Screening Program
Division of Pulmonary, Critical Care, Allergy and Sleep Medicine
Medical University of South Carolina
Core Investigator
Health Equity and Rural Outreach Innovation Center (HEROIC)
Ralph H. Johnson Veterans Affairs Hospital
Charleston, South Carolina
Chapter 118

Lynn T. Tanoue, MD, MBA
Professor of Medicine and Vice-Chair for Clinical Affairs
Department of Internal Medicine
Yale School of Medicine
Director, Lung Screening and Nodule Program
Yale Cancer Center, Yale New Haven Hospital
New Haven, Connecticut
Chapters 64 and 108

Kelan G. Tantisira, MD, MPH
Professor of Pediatrics
Chief, Department of Pediatrics
Division of Pediatric Respiratory Medicine
University of California San Diego and Rady Children's Hospital
San Diego, California
Chapter 9

Luis F. Tapias, MD
Assistant Professor of Surgery
Mayo Clinic College of Medicine and Science
Thoracic Surgeon, Mayo Clinic
Rochester, Minnesota
Chapter 80

Tachira Tavarez, MD, MSc
Clinical Associate, Neurosciences Critical Care
NIH T32 Post-Doctoral Research Fellow in Critical Care
Departments of Neurology, Anesthesiology & Critical Care Medicine
The Johns Hopkins University School of Medicine
Baltimore, Maryland
Chapter 150

Abdellatif Tazi, MD, PhD
Professor of Pulmonology, Medical School, Université Paris Cité, INSERM UMR 976
Human Immunology Pathophysiology and Immunotherapy
Head of Respiratory Department, National Reference Center for Histiocytoses
St. Louis Hospital, AP-HP
Paris, France
Chapter 59

Victor J. Thannickal, MD
Professor and Harry B. Greenberg Chair
John W. Deming Department of Medicine
Tulane University School of Medicine
New Orleans, Louisiana
Chapters 25 and 26

Sritika Thapa, MD
Clinical Instructor, Pulmonary, Critical Care, and Sleep Medicine
Yale School of Medicine
New Haven, Connecticut
Chapter 101

Jeffrey C. Thompson, MD, MTR
Assistant Professor of Medicine
Section of Interventional Pulmonology and Thoracic Oncology
Division of Pulmonary, Allergy, and Critical Care
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 77

Gregory Tino, MD
Associate Professor of Medicine
Perelman School of Medicine at the University of Pennsylvania
Chief, Department of Medicine
Penn Presbyterian Medical Center
Philadelphia, Pennsylvania
Chapters 31 and 51

Karen J. Tietze, PharmD
Professor of Clinical Pharmacy
Department of Pharmacy Practice
Philadelphia College of Pharmacy
St. Joseph's University
Philadelphia, Pennsylvania
Chapter 144

Martin J. Tobin, MD
Professor of Medicine
Division of Pulmonary and Critical Care Medicine
Loyola University of Chicago Stritch School of Medicine and Hines VA Hospital
Chicago, Illinois
Chapter 147

Kevin P. Toole
College of Science
University of Notre Dame
Notre Dame, Indiana
Chapter 58

Katrina E. Traber, MD, PhD
Assistant Professor of Medicine
Boston University
Pulmonary, Allergy, Sleep and Critical Care Medicine
Boston Medical Center
Boston, Massachusetts
Chapter 20

Bruce C. Trapnell, MD
Professor, Departments of Medicine and Pediatrics, University of Cincinnati
Attending Physician, Department of Medicine University of Cincinnati Medical Center
Attending Physician, Department of Pediatrics, Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio
Chapter 70

John Treanor, MD
Emeritus Professor of Medicine
University of Rochester Medical Center
Rochester, New York
Chapter 126

Jun-Chieh J. Tsay, MD, MSc
Assistant Professor, Department of Medicine
Division of Pulmonary, Critical Care, and Sleep Medicine
NYU Grossman School of Medicine
Department of Medicine
VA New York Harbor Healthcare System
New York, New York
Chapter 85

Homer L. Twigg III, MD
Professor of Medicine
Department of Medicine
Division of Pulmonary, Critical Care, Sleep, and Occupational Medicine
Indiana University
Indianapolis, Indiana
Chapters 22 and 63

George E. Tzelepis, MD
Professor of Medicine
National and Kapodistrian University of Athens Medical School
Athens, Greece
Chapter 83

Asad Ali Usman, MD, MPH
Instructor of Anesthesiology and Critical Care
University of Pennsylvania
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 149

Omar S. Usmani, MBBS, PhD, FHEA, FRCP, FERS
Professor of Respiratory Medicine
National Heart and Lung Institute, Imperial College London
Royal Brompton Hospital and St. Mary's Hospital London
London, United Kingdom
Chapter 45

Anil Vachani, MD, MS
Associate Professor of Clinical Medicine
Section of Interventional Pulmonology
Division of Pulmonary, Allergy and Critical Care
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 33

Judith A. Voynow, MD
Edwin L. Kendig Jr. Professor of Pediatric Pulmonary Medicine
Department of Pediatrics
Virginia Commonwealth University School of Medicine
Children's Hospital of Richmond at VCU
Richmond, Virginia
Chapter 48

Peter D. Wagner, MD
Emeritus Distinguished Professor of Medicine and Bioengineering
Department of Medicine, University of California San Diego
La Jolla, California
Chapter 14

James M. Walter, MD
Assistant Professor
Department of Internal Medicine
Division of Pulmonary and Critical Care Medicine
Northwestern University Feinberg School of Medicine
Chicago, Illinois
Chapter 128

Tisha S. Wang, MD
Professor of Clinical Medicine
UCLA Department of Medicine
UCLA Division of Pulmonary, Critical Care, and Sleep Medicine
Ronald Reagan Medical Center
Los Angeles, California
Chapter 68

John K. Waters, MD
Assistant Professor
Department of Cardiovascular and Thoracic Surgery
University of Texas Southwestern Medical Center
Dallas, Texas
Chapter 113

Timothy E. Weaver, PhD
Professor of Pediatrics (retired)
Division of Pulmonary Biology
Cincinnati Children's Hospital Medical Center
Department of Pediatrics
University of Cincinnati College of Medicine
Trout Run, Pennsylvania
Chapter 5

Andrew Weber, MD
Attending Intensivist and Pulmonologist
Department of Intensive Care and Pulmonary Medicine
Mather Hospital
Northwell Health
Port Jefferson, New York
Chapter 29

Scott T. Weiss, MD, MS
Professor of Medicine, Harvard Medical School
Physician, Department of Medicine, Brigham and Women's Hospital
Boston, Massachusetts
Chapter 44

Matthew Wemple, MD
Clinical Associate Professor of Medicine
Division of Pulmonary, Critical Care and Sleep Medicine
University of Washington School of Medicine
Intensivist, Medical Director, MICU
Pulmonary, Critical Care and Sleep Medicine
VA Puget Sound Health Care System
Seattle, Washington
Chapter 143

Jeffrey A. Whitsett, MD
Kindervelt Professor of Pediatrics
Co-Director, Perinatal Institute
Chief, Division of Neonatology and Pulmonary Biology
Cincinnati Children's Hospital Medical Center
University of Cincinnati College of Medicine
Cincinnati, Ohio
Chapter 5

Kathryn A. Wikenheiser-Brokamp, MD, PhD
Professor, Department of Pathology & Laboratory Medicine
Cincinnati Children's Hospital Medical Center and University of Cincinnati
Cincinnati, Ohio
Chapter 61

Andrew A. Wilson, MD
Associate Professor of Medicine
The Pulmonary Center and Department of Medicine
Boston University School of Medicine
Director, The Alpha-1 Center of Boston University and
Boston Medical Center
Attending Physician
Department of Medicine
Boston Medical Center
Boston, Massachusetts
Chapter 39

Christopher E. Winstead-Derlega, MD
Undersea & Hyperbaric Fellow
Department of Emergency Medicine
The Outer Banks Hospital
Nags Head, North Carolina
Chapter 92

Robert A. Wise, MD
Professor of Medicine
Johns Hopkins University School of Medicine
Attending Physician
Johns Hopkins Hospital
Johns Hopkins Bayview Medical Center
Baltimore, Maryland
Chapter 40

Christine Won, MD, MS
Associate Professor of Medicine
Section of Pulmonary, Critical Care and Sleep Medicine
Yale University School of Medicine
Chapter 47

Cameron D. Wright, MD
Professor of Surgery, Harvard Medical School
Thoracic Surgeon, Massachusetts General Hospital
Boston, Massachusetts
Chapter 80

Joanne L. Wright, MD, FRCP(C)
Professor of Pathology, University of British Columbia
Pathologist, St. Paul's Hospital
Vancouver, British Columbia, Canada
Chapter 37

Richard G. Wunderink, MD
Professor of Medicine
Department of Medicine
Division of Pulmonary and Critical Care
Northwestern University Feinberg School of Medicine
Medical Director, Medical Intensive Care Unit,
Northwestern Memorial Hospital
Chicago, Illinois
Chapter 128

Hemang Yadav, MBBS
Assistant Professor of Medicine
Division of Pulmonary and Critical Care Medicine
Mayo Clinic
Rochester, Minnesota
Chapter 94

Henry K. Yaggi, MD, MPH, BA

PREFACE

This, the 6th edition of *Fishman's Pulmonary Diseases and Disorders*, represents a major update of the prior edition. The book continues to incorporate broad and authoritative discussions of topics relevant to pulmonary physicians and those interested in sleep medicine and associated disorders; it also includes core topics of importance to the practice of critical care medicine. As in previous editions, the 6th relies heavily upon expert presentations of many basic science areas that, in the Editors' opinions, constitute an important substrate for clinically based discussions. The clinical sections of the book have been extensively revamped and expanded.

Notable content additions include important information on the respiratory effects of vaping, more detailed discussion of the idiopathic interstitial pneumonitides, an expanded presentation on the imaging and work-up of lung nodules, consideration of immunotherapy in the treatment of lung cancer, information on COVID-19–related lung disease and its management, and comprehensive discussion of noninvasive ventilation, including its use in ambulatory and ICU settings. In addition, new chapters on cystic lung disease, lung cancer screening, the lung microbiome, developmental lung disorders, nocardiosis and actinomycosis, and application of ECMO have been included. The work is extensively referenced, with more than 22,000 citations.

Remarkably, all the material presented was prepared during an unprecedented global pandemic caused by the coronavirus, SARS-CoV-2. At the time of the 6th edition's publication, more than 6.3 million deaths due to COVID-19 had been reported worldwide. The impact that the pandemic has had on all aspects of society, including health care, has been extraordinary. The fact that this edition was orchestrated during a time when those most engaged in its preparation were also heavily involved in caring for patients with coronavirus-related respiratory disease is noteworthy. The dedication of the scientists and clinicians globally who contributed to the volume during this time is duly recognized and greatly appreciated. In fact, the 6th edition is the result of contributions from 328 authors from many countries around the world, reflecting expertise that is truly global in nature; 141 are new to the publication.

Illustrations remain a pivotal component of the book, with nearly 2500 included in the book and online on *AccessMedicine.com.*

Preparation of this edition required the work of many. The Editors wish to express their sincere gratitude to the clinicians and scientists who contributed content. They are among the leading authorities on the topics on which they have written. The Editorial group itself includes three new members. Each has stepped up to the challenge and has invested considerable time and energy in helping to prepare the work. On a personal note, I'd like to express my sincere gratitude to all my Editor colleagues who collaborated in the book's development.

Finally, the Editors wish to thank key individuals on the McGraw-Hill staff who played important roles during the project, including Jason Malley, Executive Editor, Medical Publishing; Christie Naglieri, Senior Project Development Editor; and Leah Carton, Associate Editor.

Perspectives

1 **Milestones in the History of Pulmonary Medicine** 2

CHAPTER 1

Milestones in the History of Pulmonary Medicine*

Michael A. Grippi

Clinical, scientific, and technologic aspects of medicine have evolved over more than 2000 years, and the study of lung function and pulmonary diseases has been an integral part of its growth and development. About 3 centuries ago, progress toward scientific medicine accelerated markedly, and it has continued to gain speed ever since. In the 17th century, research and experimentation began to tilt clinical medicine toward the exact sciences; by the 18th century, pathology had become an integral part of clinical medicine, and clinical–pathologic correlations succeeded empiricism, dogmatism, and metaphysics. The age of the great clinicians dawned in Europe in the early 19th century, when autopsies became legal and socially acceptable, and when physicians who cared for patients actually *performed* the autopsies.

The road to our current understanding and practice of pulmonary medicine and science has been somewhat convoluted.[1–3] However, it is possible to retrace the scientific trail by examining iconic figures and addressing milestones (Table 1-1). This chapter traces the course of scientific pulmonary medicine over the last two millennia. By necessity, what follows constitutes a limited overview of *selected* aspects of the history of the field, including alveolar–capillary gas exchange, lung volumes, mechanics of breathing, control of breathing, ventilation–perfusion relationships, and scientific advancements impacting clinical medicine, including chest imaging, lung transplantation, bronchoscopic techniques, and advances in critical care. Indeed, much of the content of the book addresses the many advances in respiratory disorders achieved over the last 50 years.

ALVEOLAR–CAPILLARY GAS EXCHANGE

In reflecting on the history of the science and thinkers largely responsible for our current understanding of the central role of the lungs in gas exchange, the following are considered: the ancient Greeks, William Harvey and the Oxford physiologists, the "phlogiston theory," theories of blood gas diffusion and "secretion" of oxygen, and the physical chemistry of blood gas transport.

Ancient Greek Medicine

The beginnings of scientific medicine can be traced to ancient Greece in the sixth century BC. At that time, natural philosophers speculated that air, or an essential ingredient in air, was inspired to generate a "vital essence" for distribution throughout the body.

Hippocrates, the "father of medicine," is as much a symbol of the Greek physician of the fifth and fourth centuries BC as the name of a real figure (Fig. 1-1). As an individual, he exemplified the caring physician who kept accurate records, made cautious inferences, and relied more on nature, rest, and diet than on drugs for treatment. His name has been immortalized by affixing it to three major components of Greek medicine, even though none appears to be the work of a single individual.

The first is the *Hippocratic corpus*, a collection of about 70 works that includes case reports, textbooks, lectures, and notebooks. The collection contains a description of Cheyne–Stokes respiration and the use of *Hippocratic succussion* for the diagnosis of fluid and air in the pleural space. The second is a collection of aphorisms—a compilation of brief generalizations related to medicine. The third, which is more likely attributable to Pythagoras (c. 530 BC) than Hippocrates (who lived about a century later), is the *Hippocratic oath*, which not only represents the spirit of the physician of ancient Greece, but which has endured to modern times as a reflection of the physician's code of ethics.

Another Greek, Aristotle, not only had an enduring influence on the intellect of humankind in his own time, but also for two millennia thereafter. Not until the 17th century were Aristotle's doctrine of the four elements (earth, air, fire, and water) and that of Hippocrates (blood, phlegm, yellow bile, and black bile) laid to rest, thereby clearing the way for modern scientific medicine.

Soon after Aristotle, in about 300 BC, an extraordinary medical school was founded at Alexandria in Egypt. One of the first teachers at the school, Erasistratus, postulated that the "pneuma," or spirit essential for life, is generated from interplay between air and blood.

About four centuries after Erasistratus, Galen (Fig. 1-2) drew upon the medical, philosophic, and anatomic knowledge of his day to fashion a remarkable physiologic schema.[3,4] His construct was largely teleologic. Unfortunately, it was so convincing that even though it was ultimately proved to be fanciful, it sufficed to retard scientific progress for a millennium and a half. Galen was a talented individual who was well educated, well read, and well positioned in society to popularize his beliefs. Moreover, his concepts fit well into the tenets of Christianity, which was then in its ascendency; to controvert his authority was tantamount to blasphemy. Among his long-lasting, albeit erroneous, postulates were the following: invisible pores in the ventricular septum that enabled the bulk of the blood to flow from the right ventricle to the left ventricle, thereby bypassing the lungs; a diminutive pulmonary circulation that served only to nourish the lungs; and two-way traffic in the pulmonary veins that enabled inspired air and "effluent waste vapors" to go their respective ways (Fig. 1-3).

Voices raised in protest to Galen's theories were without lasting effect. In the 13th century, Ibn al-Nafis, writing in his *Canon of Avicenna*, objected that blood does not traverse the ventricular septum from right to left, as Galen had proposed. However, this insight attracted little attention. Three hundred years later, Vesalius voiced similar misgivings. In the 16th century, Michael Servetus, a polymath trained in theology, geography, and anatomy, pictured the pulmonary circulation as the vehicle by which the "inhaled spirit" could be distributed throughout the body. In his theologic treatise, *Christianismi Restitutio*, he pointed out that blood could not traverse the septum between the right and left ventricles, and that the lumen of the pulmonary artery was too large for a nutrient vessel. He became a hunted heretic, wanted for execution by both the Catholic Church and Calvin. He was warned by Calvin to stay out of Geneva. Both Servetus and Calvin then behaved predictably: Servetus showed up at a church where Calvin was preaching, and Calvin had him captured and burned at the stake. In 1559, Realdus Columbus of Cremona, a pupil of Vesalius, rediscovered the pulmonary circulation, as did Andreas Caesalpinus in 1571. Despite these challenging observations, Galen's schema was to last for more than another half century—until the physiologic experiments of William Harvey.

William Harvey and the Oxford Physiologists

William Harvey's (Fig. 1-4) discovery of the circulation of the blood[5] was preceded by anatomic observations on the valves in systemic veins made by his mentor, Fabricus ab Aquapedente. Harvey's

TABLE 1-1 Landmark Figures in the Evolution of Modern Pulmonary Medicine

Alveolar–Capillary Gas Exchange

Ancient Greek Medicine

- Hippocrates of Cos (c. 460–359 BC)
- Aristotle (384–322 BC)
- Erasistratus of Chios (c. 300–250 BC)
- Galen of Pergamon (AD 129–99)
- Ibn al-Nafis (c. 1210–1288)
- Leonardo da Vinci (1452–1519)
- Miguel Servetus (1511–1553)
- Andreas Vesalius of Brussels (1514–1564)
- Realdus Columbus of Cremona (1516–1559)
- Andreas Caesalpinus of Pisa (1519–1603)

William Harvey and the Oxford Physiologists

- Galileo Galilei (1564–1642)
- William Harvey (1578–1657)
- Giovanni Alfonso Borelli (1608–1679)
- Marcello Malpighi (1628–1694)
- Robert Boyle (1627–1691)
- Richard Lower (1631–1691)
- Robert Hooke (1635–1703)
- John Mayow (1640–1679)

Phlogiston: The Rise and Fall

- Georg Ernst Stahl (1660–1734)
- John Black (1728–1799)
- Joseph Priestley (1733–1804)
- Carl Wilhelm Scheele (1742–1782)

Respiration and Metabolism

- Antoine Laurent Lavoisier (1743–1794)
- John Dalton (1766–1844)
- Julius Robert von Mayer (1814–1878)
- Carl von Voit (1831–1908)
- Nathan Zuntz (1847–1920)

The Blood Gases

- Joseph Black (1728–1799)
- John Dalton (1766–1844)
- Heinrich Gustav Magnus (1802–1870)
- Felix Hoppe-Seyler (1825–1895)
- Paul Bert (1833–1886)
- Christian Bohr (1855–1911)
- John Scott Haldane (1860–1936)
- August Krogh (1874–1949)

Diffusion or Secretion of Oxygen

- Joseph Barcroft (1872–1947)
- Marie Krogh (1874–1943)

The Physical–Chemical Synthesis

- Lawrence J. Henderson (1878–1942)

Mechanics of Breathing

- John Hutchinson (1811–1861)
- Karl Ludwig (1816–1895)
- Franciscus Cornelius Donders (1818–1889)
- Fritz Rohrer (1888–1926)
- Wallace Osgood Fenn (1893–1971)

Control of Breathing

The Central Respiratory Centers

- Thomas Lumsden (1874–1953)
- Hans Winterstein (1878–1963)
- Merkel Henry Jacobs (1884–1970)

The Peripheral Chemoreceptors

- Ewald Hering (1834–1918)
- Joseph Breuer (1842–1925)
- Cornelius Heymans (1892–1968)

Scientific Basis of Clinical Medicine

Pathologic Anatomy

- Gioranni Battista Morgagni (1682–1771)
- Leopold Auenbrugger (1727–1809)
- Jean Nicolas Corvisart (1755–1821)
- René Théophile Hyacinthe Laënnec (1781–1826)

Microbiology

- Robert Koch (1843–1910)

Physiology of the Pulmonary Circulation

- Claude Bernard (1813–1878)
- Auguste Chauveau (1827–1917)
- Étienne Jules Marey (1830–1904)
- Dickinson W. Richards (1895–1973)
- André Frederic Cournand (1895–1988)
- Werner Forssmann (1904–1979)

Thoracic Imaging

- Wilhelm Conrad Roentgen (1845–1923)
- Godfrey N. Hounsfield (1919–2004)

Bronchoscopy

- Gustav Killian (1860–1921)
- Chevalier Jackson (1865–1958)
- Shigeto Ikeda (1925–2001)

Lung Transplantation

- Vladimir P. Demikhov (1916–1998)
- James D. Hardy (1918–2003)
- Joel D. Cooper

small book, *De Motu Cordis*, published in 1628, not only corrected a self-perpetuating error in Galenical teaching, but also marked the birth of modern physiology. The time, however, was not yet ripe to relate the function of the heart to the physiology of breathing. To his dying day, Harvey clung to the idea that the main function of breathing was to cool the heart. Moreover, since he made no use of the microscope, he could not picture how the pulmonary arteries made connections with the pulmonary veins. Galileo invented the compound microscope in 1610. In 1661, using the compound microscope, Marcello Malpighi reported that alveoli were covered by capillaries and that blood and air were kept separate by the continuous alveolar–capillary barrier.

Figure 1-3 Galen's scheme of the circulation. The diagram shows the source and distribution of the three types of spirits. The validity of this scheme depended on invisible pores in the ventricular septum, two-way traffic in the pulmonary vein, and selective permeability of the mitral valve for sooty wastes but not for spirit-containing blood. Vena arterialis, pulmonary vein; arteria venalis, pulmonary artery. *(Modified with permission from Singer C. A Short History of Scientific Ideas to 1900. London: Oxford University Press; 1959.)*

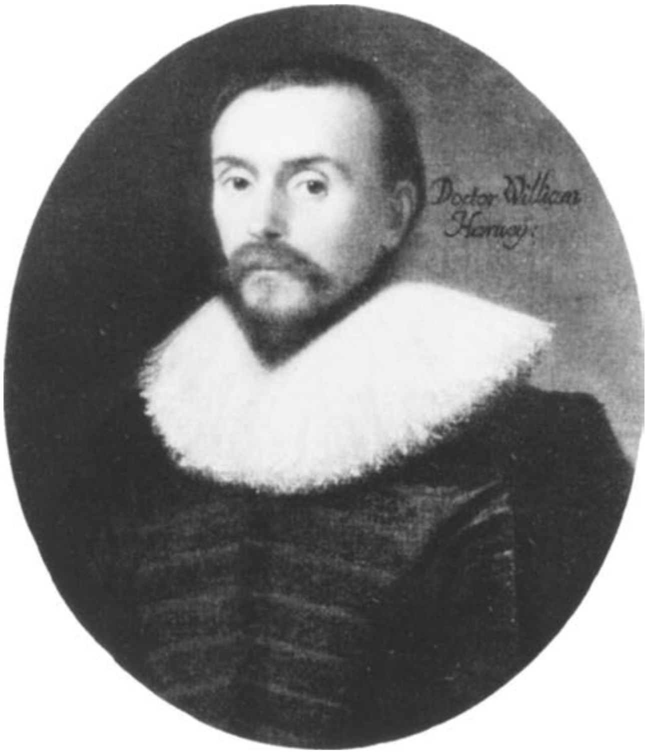

Figure 1-4 William Harvey (1578–1657). This portrait of William Harvey is part of a family group in which William Harvey and his five brothers are gathered around their father, William Harvey.

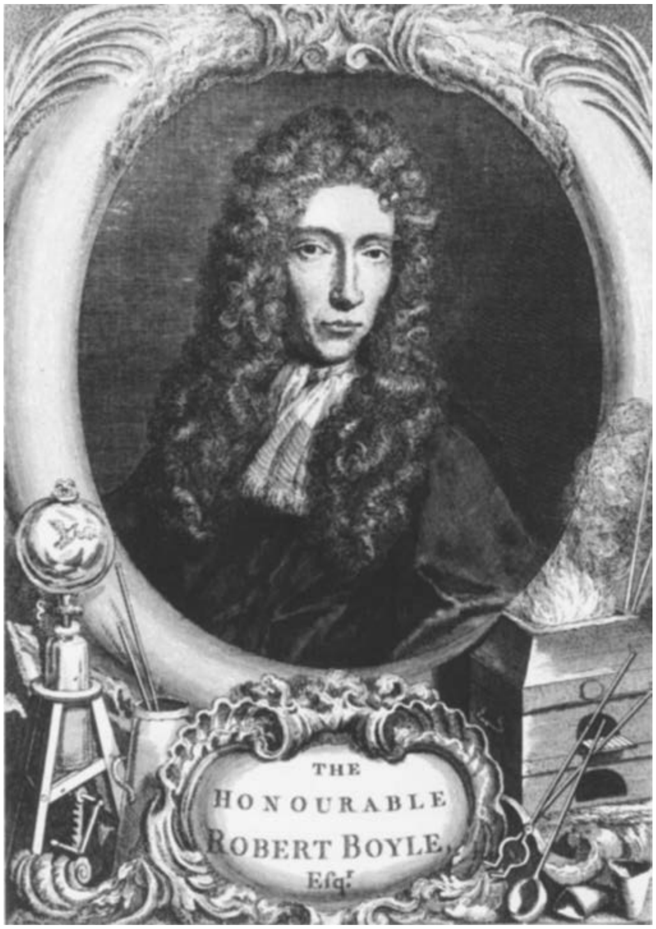

THE HONOURABLE ROBERT BOYLE, Esq.r

Figure 1-5 Robert Boyle (1627–1691). This engraving, from an original painting by Johann Kerseboom, hangs in the Royal Society, London. Boyle's invention of a pneumatic air pump and his publications concerning "the spring of air and its effect" stimulated considerable research on the physical properties of air and its role in respiration and combustion. He strongly influenced Hooke, Lower, and Mayow at Oxford.

Harvey's description in 1628 of the circulation of the blood had three major consequences for pulmonary medicine: (1) it oriented pulmonary medicine toward the basic sciences and away from philosophy and empiricism; (2) it demolished the Galenic concept of the movement of the blood; and (3) it set the stage for an upcoming generation of physiologists at Oxford University to explore breathing in chemical and physical terms.

The physiologists working at Oxford in the 1660s were greatly impressed by Harvey's disciplined approach to scientific inquiry. Many were medical practitioners who conducted research as a sideline. Four, in particular, began the systematic study of air and its constituents, thereby laying the foundations for contemporary respiratory physiology and medicine: Robert Boyle (Fig. 1-5), Robert Hooke, Richard Lower, and John Mayow.

In 1660, Robert Boyle proved by means of his air pump that air is necessary for life. In 1667, Robert Hooke showed that insufflation of the lungs with air while breathing movements were arrested could keep an open-chest animal alive; that is, that movement of the lungs was not essential for life. Richard Lower, the first to practice blood transfusion, took advantage of Hooke's continuously inflated lung preparation in the dog to observe that dark venous blood becomes bright red as it traverses lungs insufflated with air. In 1674, Mayow interpreted the change in the color of blood from venous to arterial as due to the uptake of "nitroaerial particles" (later to be called "oxygen") from the air.

■ Phlogiston: the Rise and Fall

Unfortunately, the discoveries and insights of the Oxford physiologists went largely unnoticed during the century that followed, overshadowed by the "phlogiston theory" of combustion. The theory, advanced by Stahl, postulated that all combustible materials were composed of two ingredients: phlogiston, a principle that transformed into fire when heated, and an ash that was left behind after the fiery phlogiston escaped. The phlogiston theory was sufficiently malleable to accommodate almost every new discovery that could have overthrown it, including the rediscovery of carbon dioxide in 1754 by John Black, and the independent discoveries of oxygen by Priestley and Scheele. Although the respiratory gases had been discovered by the end of the 18th century and many of their properties characterized, the discoveries were misapplied to support, rather than destroy, the phlogiston theory. The phlogiston theory was finally undone by the experiments of Lavoisier.

■ Respiration and Metabolism

From the time of Hippocrates until early in the 20th century, debate had continued about the site of heat production in the body. In 1777, Lavoisier suggested that air was composed of one respirable gas (which he later named "oxygine") and another (nitrogen) that remained unchanged in the course of respiration. Between 1782 and 1784, Lavoisier and Laplace concluded, on the basis of calorimetric experiments on guinea pigs, that "respiration is therefore a combustion, admittedly very slow, but otherwise exactly similar to that of charcoal" (Fig. 1-6). The similarity between respiration and combustion had previously been recognized by the Oxford physiologists, especially Mayow.[6] By 1783, Lavoisier was accumulating evidence against the phlogiston theory and began to replace it with an entirely new system of chemistry.

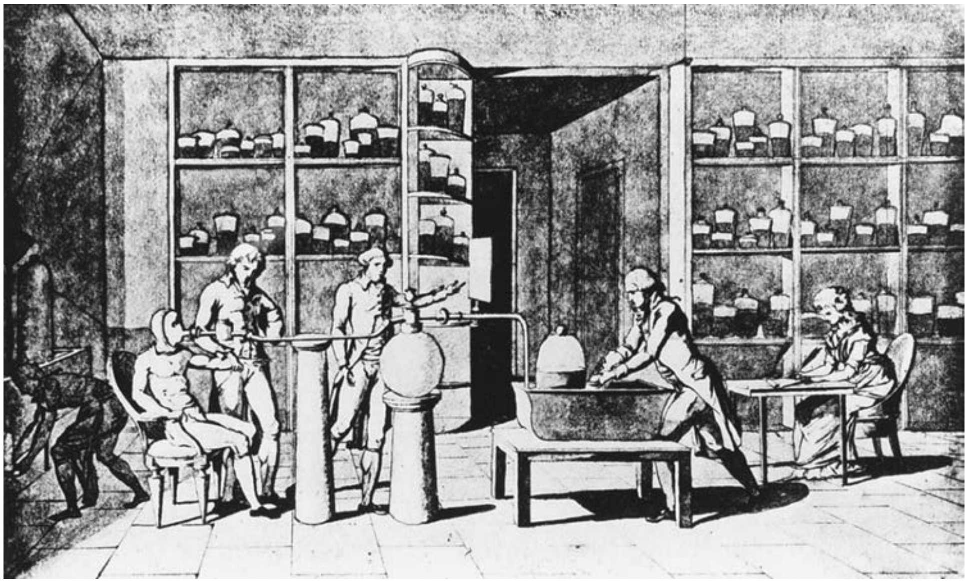

Figure 1-6 Scene from the laboratory of Antoine Laurent Lavoisier (1743–1794). His wife is acting as his assistant, and Sequin is the subject. Studies such as this led to the conclusion that respiration and combustion are similar processes.

As noted previously, the ancients pictured the heart as the heat generator. Lavoisier favored the lungs. Others held that combustion occurred in the blood. Although Spallanzani had shown in the 18th century that isolated tissues take up oxygen and evolve carbon dioxide, the idea that combustion occurred in the tissues was slow to gain acceptance. However, the hypothesis gained strength through the work of Pflüger in 1878. He measured oxygen consumption and carbon dioxide production in dogs and calculated respiratory quotients. His research substantiated a concept that had been enunciated, but not named, by Lavoisier.[7]

Once the idea that oxidation occurred in the tissues had become generally accepted, investigators delved into the processes involved in utilization of foodstuffs by the tissues, energetics, growth, and repair. Carl von Voit and Max von Pettenkofer, using a respiration chamber, drew upon chemical balances and respiratory quotients in humans to distinguish the nature of the foodstuffs being burned and to show that the amounts of fat, protein, and carbohydrate burned varied with the mechanical work done by the subject. Between 1842 and 1845, Julius Robert von Mayer formulated the law of conservation of energy. Subsequently, Max Rubner showed that the law applied to the living body, and Herman von Helmholtz showed that its relevance to metabolism could be demonstrated experimentally. Application of these principles at the bedside was greatly facilitated by the development of a portable metabolic apparatus by Nathan Zuntz. Pioneering bedside studies of metabolic states were conducted by a succession of distinguished investigators, including Magnus-Levy, Graham Lusk, F. G. Benedict, and Eugene F. DuBois.

■ The Blood Gases

The Oxford physiologists set the stage for the discovery of the blood gases. Using his vacuum pump, Robert Boyle extracted "air" from blood. John Mayow came close to discovering oxygen by showing that only a portion of air was necessary for life—the "nitroaerial spirits"—which were removed both by respiration and fire (combustion). One of his famous experiments entailed enclosing a mouse and a lighted lamp in an airtight container; the lamp went out first and then the mouse died. However, Mayow did not realize that the "nitroaerial spirits" could be isolated as a gas.[6]

One hundred years after Mayow, Joseph Priestley (Fig. 1-7) exposed a mouse to the gas released from heated mercuric oxide and found that the gas supported life better than air did; he also noticed that a flame burned more vigorously in this gas than in air. Priestley was not alone in his preoccupation with flame. In 1773, about a year before Priestley had obtained oxygen by heating mercuric oxide, Scheele discovered oxygen independently because of his interest in fire, and he designated oxygen as "fire air."

In 1662, Van Helmont, a Capuchin friar and talented chemist, as well as a mystic with a drive to quantify, discovered carbon dioxide, coined the word *gas*, and called carbon dioxide "wild gas" ("gas sylvestre"). In 1755, Joseph Black rediscovered carbon dioxide. He showed that calcium carbonate (limestone) and magnesium carbonate (magnesia alba) lost weight on heating, releasing "fixed air" (CO_2) in the process. This fixed air extinguished both flame and life. Lavoisier knew of the observations of Black and of Priestley

JOSEPHUS PRIESTLEY
C. G. HANCOCK F.

Figure 1-7 Joseph Priestley (1733–1804), the discoverer of oxygen. This figure shows a silver medal struck in his honor in 1783. A Presbyterian minister, he was radical in his religious and political beliefs, inventive in science, and conservative in the interpretation of his findings. *(Reproduced with permission from Fishman AP, Richards DW. Circulation of the Blood: Men and Ideas. New York, NY: Oxford University Press; 1964.)*

Figure 1-8 Christian Bohr (1855–1911). At work in his laboratory, Bohr *(far right)* and his associates systematically explored the interplay between the respiratory gases and hemoglobin that led to the discovery of the “Bohr effect.” *(Reproduced with permission from Fishman AP, Richards DW. Circulation of the Blood: Men and Ideas. New York, NY: Oxford University Press; 1964.)*

and Scheele. He decided in 1778 that the gas obtained from heating mercuric oxide was not “fixed air” or “common air,” but “highly respirable air” (oxygen).

The story of hemoglobin, the essential element in the transport of the respiratory gases by the blood, begins with Hoppe-Seyler, who, between 1866 and 1871, crystallized hemoglobin, explored its chemical properties, and assigned it a proper role in the transport of oxygen by the blood. At the turn of the 19th century, Dalton reported his experiments with the respiratory gases, which led to the development of his atomic theory. In 1872, taking advantage of Dalton’s law, Paul Bert published the first oxygen dissociation curve, that is, oxygen content at different barometric pressures; he pictured the curve as hyperbolic. Christian Bohr (Fig. 1-8) subsequently identified its s-shaped contour, and in 1904, together with Hasselbach and August Krogh, showed that increasing carbon dioxide tension in blood drives out oxygen, that is, the “Bohr effect.” Shortly thereafter, the influence of various factors, for example, temperature and electrolytes, on the affinity of oxygen for hemoglobin (and, consequently, on the position of the oxygen dissociation curve) was explored in detail by Barcroft and associates. In 1914, Christiansen, Douglas, and Haldane reported that an increase in the oxygen tension of the blood drives out carbon dioxide, that is, the “Haldane effect.” In 1967, a new dimension was added to the understanding of the position and configuration of the oxygen dissociation curve by the demonstration that diphosphoglycerate, a chemical constituent of red cells, regulates the release of oxygen from oxyhemoglobin.

■ Diffusion or Secretion of Oxygen

Bohr is a central figure as an investigator and mentor in respiratory physiology.[8] In 1904, he raised a troublesome issue that was not easily resolved, primarily because of limitations in methodology at the time. He postulated that even though diffusion could account for oxygen uptake at rest, it could not suffice during strenuous exercise, particularly at altitude. He held that oxygen *secretion* had to be involved.[9] He clung to this misconception during his lifetime, a conviction supported by two major lines of evidence. The first was indirect: Oxygen secretion by the swim bladder of fish showed by extrapolation that active transport of oxygen in the lungs was possible. The second was based on observations made during Bohr’s expedition to Pike’s Peak in 1912, during which it was erroneously demonstrated that with exercise at altitude, arterial oxygen tension exceeded alveolar oxygen tension.

However, even before the report from high altitude, Bohr’s former assistant, August Krogh, and his wife, Marie Krogh (Fig. 1-9) had marshaled new evidence to show that “the absorption of oxygen and the elimination of carbon dioxide in the lungs takes place by diffusion and diffusion alone.” The final blow to the secretion theory was delivered by Marie Krogh.[10] Based on the single-breath carbon monoxide method for determining diffusing capacity that she and her husband had developed in 1910,[11] she was able to account for oxygen uptake in the lungs by diffusion alone, even during strenuous exercise under conditions of low oxygen tension. Refinements in the carbon monoxide method by Roughton and others extended

Figure 1-9 August and Marie Krogh in 1922, at the time of their first visit to the United States so that August Krogh could deliver the Silliman Lecture at Yale. They demonstrated that diffusion, without secretion, could account for the transfer of O_2 and CO_2 across the alveolar–capillary membranes of the lungs. *(Reproduced with permission of their daughter, Dr. Bodil Schmidt-Nielsen.)*

Figure 1-10 Two founders of contemporary respiratory physiology in 1936. Sir Joseph Barcroft (1872–1947) *(left)* proved, in experiments on himself, that diffusion was the mechanism for gas exchange in the lungs and pioneered current understanding of the respiratory functions of the blood. Lawrence J. Henderson (1878–1942) *(right)* provided a mathematical analysis of blood as a physiochemical system and stimulated research on the complex interplay involved in respiratory gas exchange during exercise. *(Reproduced with permission from Fishman AP, Richards DW. Circulation of the Blood: Men and Ideas. New York, NY: Oxford University Press; 1964.)*

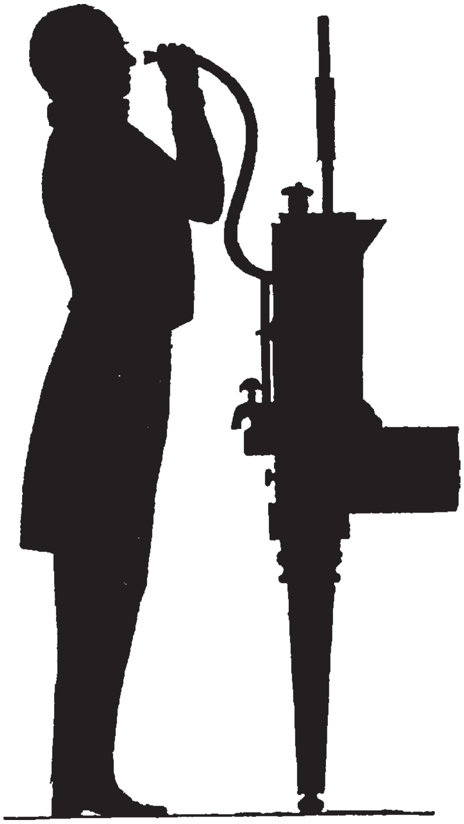

Figure 1-11 John Hutchinson's illustration of a subject about to undergo measurements of lung volumes. *(Reproduced with permission from Hutchinson J. On the capacity of the lungs, and on the respiratory functions, with a view of establishing a precise and easy method of detecting disease by the spirometer. Med Chir Trans. 1846;29:137–252.)*

its clinical applicability and provided further evidence against the secretion theory.[12] Despite these observations, Haldane would not let go. Throughout his life, despite mounting evidence to the contrary, he adhered to the idea that oxygen was secreted by the alveolar membrane.

The issue was finally settled by Joseph Barcroft (Fig. 1-10). Using a chamber to reproduce the circumstances of hypoxia and strenuous exercise assessed during the Pike's Peak expedition, he found that under all conditions, the oxygen saturation of arterial blood was less than that of arterial blood exposed to a sample of alveolar gas obtained at the same time. He subsequently confirmed these results by experiments done at high altitude at Cerro de Pasco (1921–1922).

■ The Physical–Chemical Synthesis

Lawrence J. Henderson undertook the herculean task of depicting the reactions of oxygen and carbon dioxide in blood, not as cause and effect, but as interplay among physiochemical variables and functions (Fig. 1-10). His theoretical considerations and practical applications in the Fatigue Laboratory at Harvard University were greatly abetted by close collaboration with Van Slyke, Wu, and McLean at the Rockefeller Institute in New York, who were exploring the exchanges of blood constituents between red cells and plasma. In 1828, Henderson presented his synthesis in the form of a d'Ocagne nomogram that displayed changes in the various elements that entered into the exchange of the respiratory gases between alveolar gas and blood: plasma; the red cell; hemoglobin; and chloride, bicarbonate, and hydrogen ions. He presented nomograms not only for the normal subject at rest and during exercises, but also for individuals with anemia, nephritis, diabetic coma, and other major clinical entities. Henderson dealt with steady-state observations. Roughton and associates enlarged the physiochemical horizons further by discovering carbonic anhydrase in the red cell and addressing transient phenomena related to transport of respiratory gases and carbon monoxide in blood.

LUNG VOLUMES

Although Humphrey Davy had determined his own lung volume using hydrogen as the test gas in 1800,[13] it was not until the 1840s that John Hutchinson laid the groundwork for modern pulmonary function testing. He devised a spirometer and used it to determine the subdivisions of the lung in a large number of healthy subjects, relating the measurements to height and age (Fig. 1-11). The many refinements since then are too numerous for mention in this chapter. A big step forward was the invention of the body plethysmograph many years later, which made possible the determination of the thoracic gas volume and airway resistance.

MECHANICS OF BREATHING

The ancients wondered how air moved into and out of the lungs; as far back as the time of Erasistratus, the diaphragm was recognized as involved in breathing. Galen was aware that the lungs fill the chest cavity and are moved by the actions of the thorax, and that the large airways enlarge and lengthen during inspiration. He marveled at the long course of the nerves to the diaphragm and the innervation of the intercostal muscles. After Galen, interest in the mechanics of breathing waned except for sporadic observations and experiments by anatomists, notably Leonardo da Vinci and Andreas Vesalius. Interest in respiratory mechanics resumed in the 16th century, largely as a result of progress in physics and mathematics, as exemplified in the works of Borelli and Galileo.

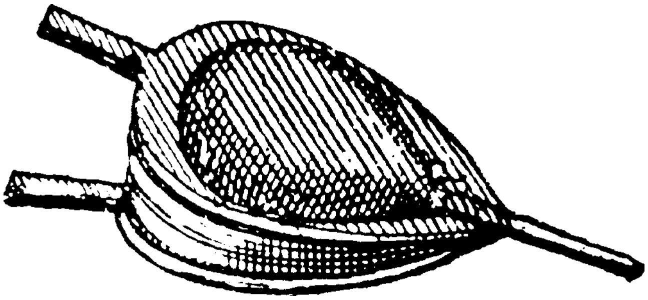

Figure 1-12 Mayow's model of the chest and lungs. The bellows encloses a bladder, the neck of which opens to the outside. A glass window on the upper side makes it possible to observe the bladder during inflation and deflation. *(Reproduced with permission from Mayow J: Medico-Physical Works, Crum A, Brown, Dobbin L [trans]. ■ The Respiratory Muscles

Mayow, one of the Oxford physiologists, drew heavily on the work of colleagues, including Boyle and Hooke, to develop considerable insight into the mechanics of breathing. He also built the first model on record of the chest as a bellows, which contained a bladder within it (Fig. 1-12). He understood that air moved into the lungs as the chest expanded because of the pressure and elasticity of ambient air; he also appreciated that the chest expands because of the action of the intercostal muscles (internal and external), that the diaphragm is the primary muscle of inspiration, and that normal expiration is passive. After Mayow, little research was done on the role of the respiratory muscles in breathing until the mid-19th century, when Donders distinguished between the respective roles played by the inspiratory muscles and elastic forces.

■ Elastic Properties of Lungs and Chest Wall

Until the 20th century, observations on the elastic properties of the lungs and chest wall in humans were fragmentary. Access to the pleural space was the major limiting factor. With few exceptions—notably Neergaard and Wirz, who used pleural pressures to determine elastic recoil in normal human subjects, and Christie, who recorded pleural pressures to demonstrate loss of pulmonary elasticity in emphysematous patients—measurements in humans were largely confined either to therapeutic interventions, for example, induction of a pneumothorax or aspiration of pleural fluid, or experiments done at autopsy. The number of observations on the mechanical properties of the lungs increased dramatically when it was shown by Buytendijk, in 1949, and again by Dornhurst and Leathart, in 1952, that esophageal pressures provided an accurate measure of pleural pressures.

The role of alveolar surface tension in determining the elastic forces in the lungs began to be widely appreciated in the late 1950s, although the stage had been set long before. In 1812, Laplace had published the law of surface tension. The implication of this law for the lungs was appreciated initially in 1929 when Neergaard compared pressure–volume curves of lungs filled with air with those filled with fluid. He concluded that unopposed surface tensions would favor alveolar collapse. Then, between 1954 and 1960, a remarkable outpouring of papers from different laboratories showed that a unique surfactant lined the alveoli, and that this material was absent in premature infants with hyaline membrane disease (and alveolar collapse); these papers prompted extensive research on the chemical and physical properties of surfactant and on its sites of formation and removal.

■ Airway Resistance

A giant step forward occurred in 1916 when Rohrer, as part of his doctoral dissertation, presented a conceptual framework for determining flow and resistance in airways. His equations were based on precise anatomic measurements of airway dimensions in a human cadaver, coupled with aerodynamic principles. During the following decade, he and his coworkers, Neergaard and Wirz, applied Poiseuille's law for laminar flow and his equations to the determination of airway resistance. Use of Fleisch's pneumotachograph, coupled with periodic interruptions of airflow, permitted measurement of alveolar pressure. Clinically useful measurements of alveolar pressure became available in 1956 with the introduction by DuBois and associates of the whole-body plethysmograph, which they coupled with the application of Boyle's law.

■ Synthesis of Mechanics

During the decade between 1915 and 1926, Rohrer and his colleagues provided a remarkably comprehensive synthesis of respiratory mechanics that included a description of the static pressure–volume characteristics of the respiratory system and the work of breathing; they also developed the principle of optimal frequencies of breathing to minimize respiratory work. Together with von Neergaard and Wirz, Rohrer developed and tested, experimentally, concepts involving pressures, flows, and volumes. The full significance of Rohrer's work was not appreciated until the publications by Fenn and his group at the University of Rochester, starting in the 1940s. The contributions of W. O. Fenn, H. Rahn, and A. B. Otis to our present understanding of the mechanics of breathing are significant, and there is little doubt that this group shaped much of the contemporary thinking of respiratory physiologists and pulmonary physicians.[14–17]

CONTROL OF BREATHING

The control of breathing is a complex process that depends on the integrity of the entire respiratory system—lungs, airways, circulation, and control systems.[18] Two dominant control systems exist. One is in the central nervous system; the other is outside the brain. Control mechanisms in the central nervous system are influenced by the state of wakefulness or alertness and are subject to voluntary control. These mechanisms are also influenced reflexively by a variety of peripheral receptors.

■ Localization of the Central Respiratory Centers

In 1812, Legallois, apparently intrigued by the gasping movements of the head after decapitation, identified an area in the medulla that was essential for life. In 1923, Lumsden systematically explored the effects of serial sectioning of the brain stem on respiration, marking the beginning of the era of contemporary research on rhythmic breathing. He designated an area in the caudal pons responsible for a sustained inspiratory drive as the "apneustic center," and an area in the rostral and lateral portions of the pons that presumably inhibited the apneustic drive as the "pneumotaxic center"; sectioning of the vagi exaggerated the inhibition of the apneustic drive by the pneumotaxic center. Sixteen years later, Pitts et al.,[19] using stereotactic stimulation of the cat medulla, identified inspiratory and expiratory centers and proposed a theory that could account for both rhythmic breathing and apneusis.

■ Chemical Stimulation of the Respiratory Centers

The chemical stimuli to breathing have been known for more than a century. In 1885, Miescher-Ruesch showed in humans that ventilation at rest is primarily regulated by carbon dioxide. Between 1887 and 1901, cross-perfusion experiments by Leon Fredericq underscored the role of carbon dioxide. However, it was not until 1905 to 1909 that Haldane, Priestley, and Douglas paved the way to the modern understanding of the role of carbon dioxide under a variety of experimental conditions.[20] In their experiments on humans, they relied heavily on the Haldane gas analyzer and an alveolar gas sampler of their own invention. However, their experiments did not distinguish clearly between CO_2 and H^+ in the stimulation of the respiratory centers. Winterstein, and later Gesell,[21] advanced the idea that the chemical regulation of respiration is determined by the concentration of hydrogen ions within the respiratory centers.

The Winterstein theories[22] provide a good example of the evolution of ideas prompted by new discoveries and inventions. The original theory in 1911 attributed increments in ventilation caused by hypoxic or hypercapnic inspired mixtures to a single mechanism, that is, acidification of arterial blood by either carbonic acid or lactic acid. In 1921, Jacobs' demonstration of the rapid diffusion of carbon dioxide into starfish eggs implicated acidity within the respiratory centers,[23] as well as arterial blood acidity, as the sites of stimulation. To account for the stimulation of breathing by hypoxia (the peripheral chemoreceptors had not yet been discovered), he invoked the release of asphyxiating substances *(Erstickungsstoffen)* within the respiratory centers themselves. A third theory, postulated in 1949, attempted to incorporate the discovery of the peripheral chemoreceptors, and it finally gave way in 1955 to his fourth theory, which explained the effects of acid or hypoxia on both the central and peripheral chemoreceptors.

A major consequence of Winterstein's research was an impetus to subsequent exploration of the chemical control of breathing. These studies led to the identification of central chemoreceptors, distinct from mechanoreceptors, on the ventral surface of the medulla, and clarification of the role of hydrogen ion activity as the central stimulus to breathing. The studies also prompted a search for a unifying theory for the chemical control of breathing.

■ The Reflex Regulation of Breathing

A considerable and diverse number of peripheral receptors can influence breathing reflexively by supplying information to respiratory centers located in the brain. These include pain receptors, stretch receptors in the muscles and distensible thoracic structures, and organs and chemoreceptors in major systemic arteries.

■ Mechanoreceptors

Until the work of Hering and his student, Breuer, little was known about the role of afferent impulses to the central control mechanisms in the control of breathing, other than the fact that electrical stimulation of the vagus nerves influenced respiration.[24] In 1868, Hering and Breuer reported that inflation of the lungs stopped respiration in expiration and promoted expiration, and that, conversely, a decrease in lung volume ended expiration and promoted inspiration. They inferred that inflation mechanically stimulated nerve endings in the lungs and that the resulting impulses ascending the vagi were inhibitory to inspiration.

■ Peripheral Chemoreceptors

In 1841, Volkmann suggested the existence of chemoreceptors in the systemic circulation that were sensitive to blood-borne stimulants to respiration. In 1927, J. F. Heymans and C. Heymans first showed that the aortic bodies served this function, and in 1930, C. Heymans and Bouckaert demonstrated the peripheral chemoreceptive function of the carotid bodies. These were physiologic observations that tallied well with the observations of F. De Castro, a student and later a colleague of Ramón y Cajal, who was sufficiently impressed by the histologic structure, location, and rich innervation of the carotid body to propose that it might be stimulated by blood-borne substances (Fig. 1-13).[25]

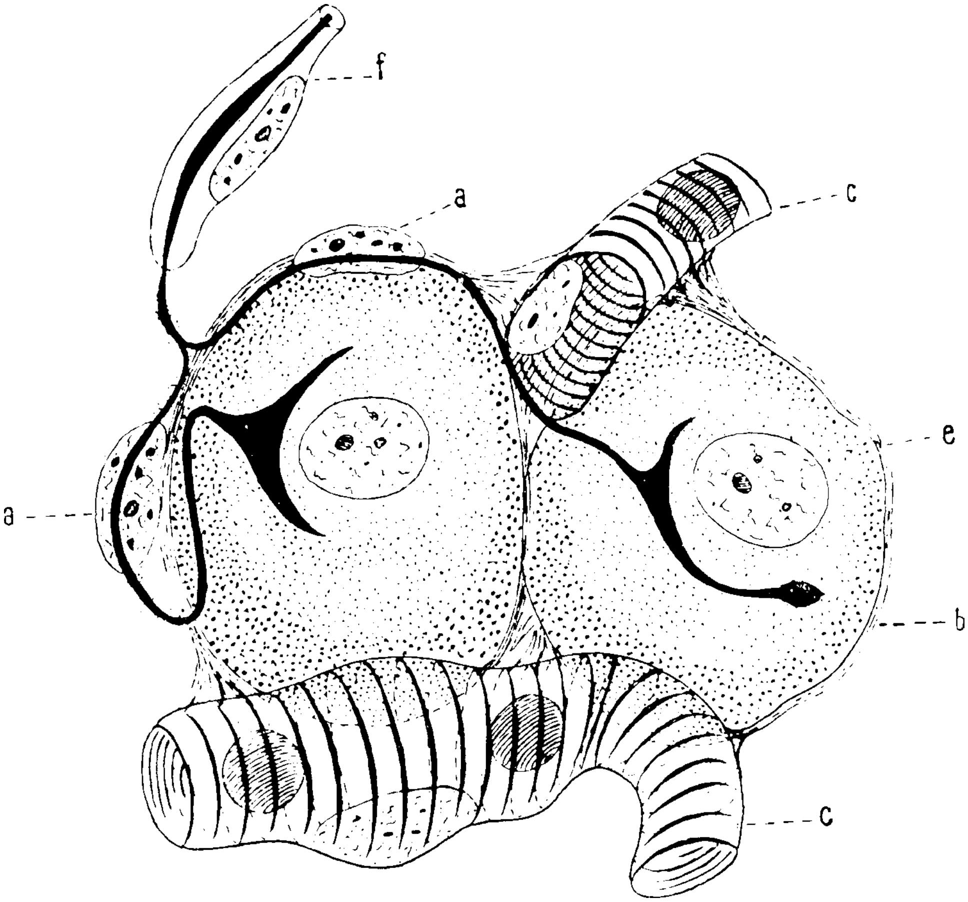

Figure 1-13 Drawing by De Castro showing the structure of the chemoreceptor. The glomus cells (*e*) present an ample cytoplasmic surface for contact with the perfusing blood delivered by the capillary (*c*); sensory nerve fiber (*f*) with sheath of myelin; Schwann cells (*a*) surround the unmyelinated fibers which form the terminal menisci; cell membrane (*b*). *(Reproduced with permission from De Castro F: Sur la structure de la synapse dans les chemocepteurs: leur mécanisme d'Excitation et R™ le dans la circulation sanguine locale. Acta Physiol Scand. 1951;22(1):14–43.)*

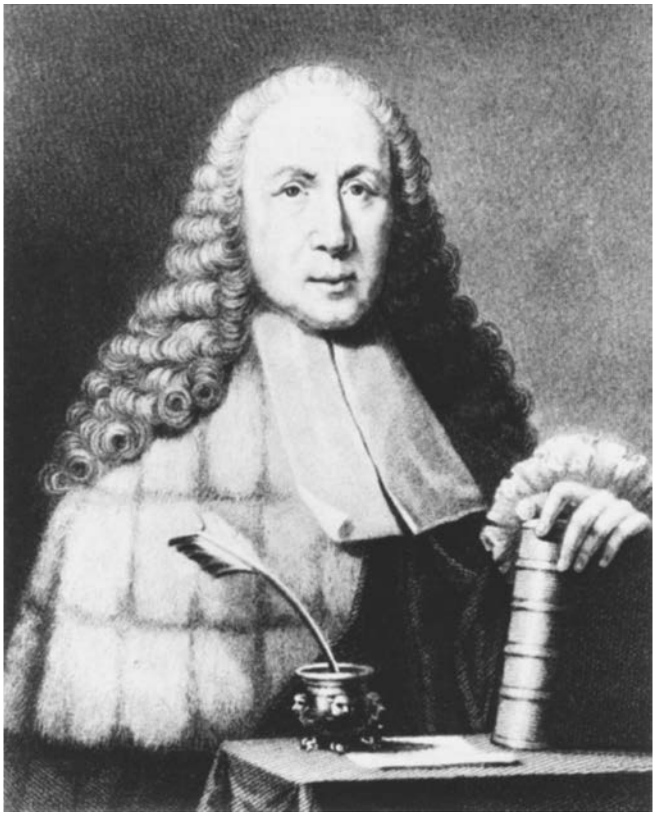

Figure 1-14 Giovanni Battista Morgagni (1682–1771). The five volumes of his *De Sedibus* contain the clinical and pathologic descriptions of approximately 700 cases. *(Reproduced with permission from the Library of the College of Physicians of Philadelphia.)*

VENTILATION–PERFUSION RELATIONSHIPS

In 1946, William Dock attributed the apical localization of tuberculosis to hypoperfusion of well-ventilated alveoli in the lung apices in the upright position.[26] Shortly thereafter, ventilation–blood flow relationships were described in quantitative terms in papers by two separate groups: Rahn and Fenn[27] and Riley and Cournand.[28–30]

SCIENTIFIC BASIS OF CLINICAL PULMONARY MEDICINE

Five remarkable figures serve to illustrate different stages in the evolution of the scientific basis of pulmonary medicine: Morgagni, Laënnec, Koch, Cournand, and Richards. They represent key scientists in the areas of pathologic anatomy, microbiology, and physiology.

■ Pathologic Anatomy

Morgagni and Laënnec, almost a century apart, made major contributions to the field of pathologic anatomy. Morgagni (Fig. 1-14), who lived in the 18th century and was a student of Valsalva, veered away from the undisciplined case reports of his predecessors. Instead, he adopted a logical system for relating findings at autopsy to their clinical manifestations. At age 79, he published a compilation of his lifelong experience in his famous work, *De Sedibus et Causis Morborum per Anatomen Indagatis. De Sedibus* includes about 700 cases. The clinical–pathologic correlations in this work benefited greatly from the fact that Morgagni was both a seasoned clinician and a pathologist. One of the compilation's five books is devoted to diseases of the thorax. Among his descriptions were those of a tubercle undergoing liquefaction and the hepatization stage of pneumonia.

René Théophile Laënnec is, perhaps, best known for inventing the stethoscope in 1816 (Fig. 1-15).[31,32] At that time, clinical medicine in Europe, especially in France, was turning from metaphysical concepts and doctrinal systems to pathology as its scientific foundation. Eminent physicians, such as Bichat, Bayle, and Corvisart in France, and William and John Hunter and Baillie in England, were turning to anatomic findings at autopsy to understand the signs and symptoms of their patients. Percussion had been rediscovered by Corvisart. Although Auenbrugger had reported in Latin his "new invention" in 1761, the idea had not caught on until Corvisart—eminent clinician and teacher and personal physician to Napoleon—published a translation in French in 1808. Corvisart's approach to medicine strongly influenced Laënnec. Laënnec applied the stethoscope and Corvisart's "sounding of the chest" to study individual patients with diseases of the lungs and heart throughout their clinical course, along with anatomical examination at autopsy. This was no simple matter. Since there were no pathologists in those days, the physician not only had to provide continuous care during the patient's lifetime, but he also had to arrange for, and perform, the autopsy; he then had to gather all that he had seen and learned and prepare it for publication.

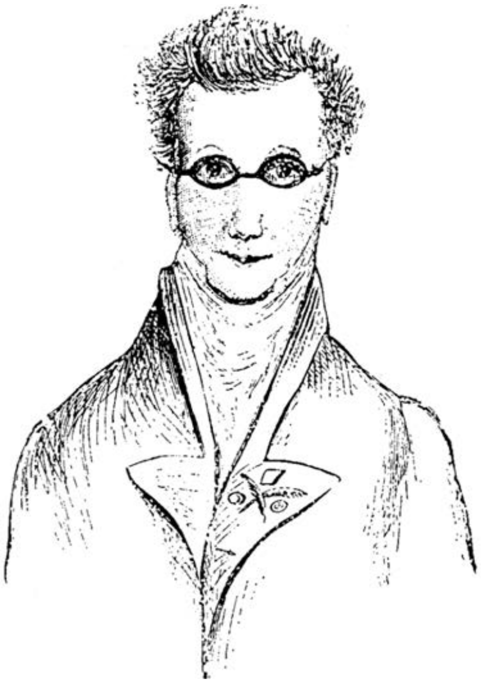

Figure 1-15 Rene T.H. Laënnec (1781–1826). *(Drawn from life in 1825 by Charles James Blasius Williams (1805–1889) and reproduced in his autobiography, Memoirs of Life and Work, London: Smith, Elder & Co; 1884.)*

In 1819, two years after the invention of the stethoscope, Laënnec published his famous monograph, *De l'Auscultation médiate*, which drew lessons from carefully documented cases that were studied throughout their clinical course and at autopsy. In this work, Laënnec built upon the monumental tome of Morgagni, who, a generation before, had related the clinical features of the diseases he described to the morbid anatomy, but who had not been able to take the next step of relating the clinical course of individual patients to the anatomic findings after death.

Laënnec's monograph contains descriptions of physical signs, clinical–pathologic correlations for tuberculosis, pneumonia, bronchiectasis, emphysema, and cancer of the lung, and instructions for the treatment of these conditions. The descriptions of tuberculosis were an outstanding contribution to the field and were reported prior to Koch's discovery of the causative agent.

■ Microbiology

Tuberculosis provides a remarkably illuminating example of the impact of a novel basic science on clinical medicine.[33–35] The disease can be traced back to the ancients, who were familiar with the diverse clinical syndromes that we now take for granted as due to tuberculosis; however, they had no way to relate them to a common etiologic agent. A synthesis by Morton in 1685 of all that was then known about tuberculosis focused on cavitary lesions, emaciation ("consumption"), and the tubercle, but it was shrouded in Galenic humors. An understanding of the disease accelerated in the 18th century when clinicians, such as William Cullen, began to sort out the various syndromes relating to phthisis, including hemoptysis, empyema, catarrh, and asthma.

The tempo of discovery increased dramatically in the 19th century after the French Revolution. During the Napoleonic era, distinguished Parisian clinicians, including Bichat, Bayle, Louis, Broussais, and Laënnec, reported clinical–pathologic correlations of tuberculosis. (Notably, both Bayle and Laënnec died of tuberculosis.) However, little advance was made in understanding the pathogenesis of tuberculosis until Villemin, who, impressed by the analogy between glanders and syphilis on the one hand, and tuberculosis on the other, and the fact that two of the three diseases had been shown to be infectious in origin, undertook experiments demonstrating that tuberculosis was an infectious disease that could be transmitted from humans to animals, and from animals to animals.

Koch

In 1876, Koch was a general practitioner in the German township of Wollestein in the province of Posen, where he was responsible for the health care of 4000 inhabitants (Fig. 1-16). Between obstetrical deliveries and satisfying the medical and surgical needs of patients of all ages, he managed to conduct research on the microbial causes of communicable diseases. His laboratory was homemade—based in either the barn or his living room; his major instrument was a microscope used to examine bacteriologic and tissue specimens. In pursuing his research, he kept in mind the dictum of Jacob Henle, one of his teachers in medical school, who counseled that, "before microscopic organisms can be regarded as the cause of contagion in man, they must be found constantly in the contagious material, they must be isolated from it and their strength tested." This lesson was to become the keynote of the future "Koch postulates."

In 1876, Koch, the busy medical practitioner, sent a letter to Professor Ferdinand Cohn, director of the Botanical Institute in Breslau, indicating that he had discovered "the process of development of bacillus anthracis" and requesting permission to present his findings to Professor Cohn, "the foremost authority on bacteria." Koch had discovered the spores of anthrax bacilli. Cohn arranged for him to present his results before a room full of formidable, distinguished scientists, including Julius Cohnheim, Carl Weigert, Moritz Traube, Ludwig Lichtheim, and Leopold Auerbach. Koch's demonstration of the complete life history of the anthrax bacillus, including sporulation, was entirely convincing to these scientists. After the meeting, Cohnheim, upon his return home, announced to his colleagues, "This man has made a splendid discovery which is all the more astonishing because Koch has had no scientific connections and has worked entirely on his own initiative and has produced something absolutely complete. There is nothing more to be done. I consider this the greatest discovery in the field of bacteriology."

During the next 2 years, Koch described novel procedures for the examination, preservation, and photography of bacteria and demonstrated the role of microorganisms in traumatic infections, while continuing his dual existence as a country doctor and an independent investigator. In 1880, Cohn and Cohnheim arranged for him to move to Berlin as a member of the Imperial Sanitary Commission. The move freed more time for research. By 1881, he made another breakthrough—the pour-plate method for isolating pure cultures. The opportunity that this technique afforded to produce transparent solid media, coupled with Koch's invention of new staining methods, paved the way for him to tackle the microbial cause of tuberculosis.

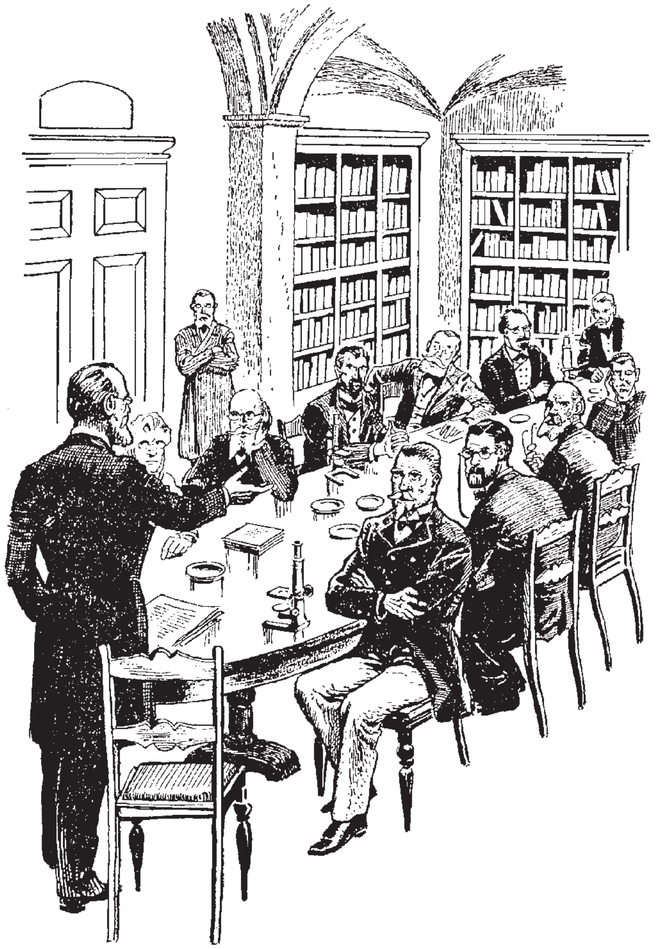

Figure 1-16 Robert Koch (1843–1910), announcing his discovery of the tubercle bacillus as the cause of tuberculosis, Berlin, March 28, 1882. *(Reproduced with permission from Knight D: Robert Koch: Founder of Bacteriology. New York, NY: Franklin Watts, Inc; 1961.)*

Koch's scientific approach, which has been immortalized as "Koch postulates," consisted of four essential steps: (1) To prove that a microbe is the cause of a disease, it must be present in all cases of the disease. (Koch showed this for the tubercle bacillus using methylene blue and a counter stain.) (2) The microbe must be grown outside of the body in pure culture. (Koch devised blood-serum jelly as a culture medium for the slow-growing tubercle bacillus.) (3) The pure culture must be capable of causing the disease in healthy animals. (Koch proved this initially by inoculation and, subsequently, by allowing animals to breathe contaminated air.) (4) The same microbe must then be isolated from the inoculated (infected) animal and grown outside of the body in pure culture.

Koch's discovery of the tubercle bacillus and its modes of transmission revolutionized the treatment of tuberculosis. Before the discovery, tubercular patients were treated in sanitaria, which offered fresh air and altitude. Those who ran the sanitaria did not know that tuberculosis was a contagious disease: Sanitation was unregulated, and neither sterilization nor fumigation was practiced; diagnostic capabilities were limited. Koch's discovery of the tubercle bacillus revolutionized therapy. For the rest of his life, while pursuing the causes of other diseases around the world—rinderpest in South Africa, Texas fever, tropical malaria, blackwater fever, and bubonic

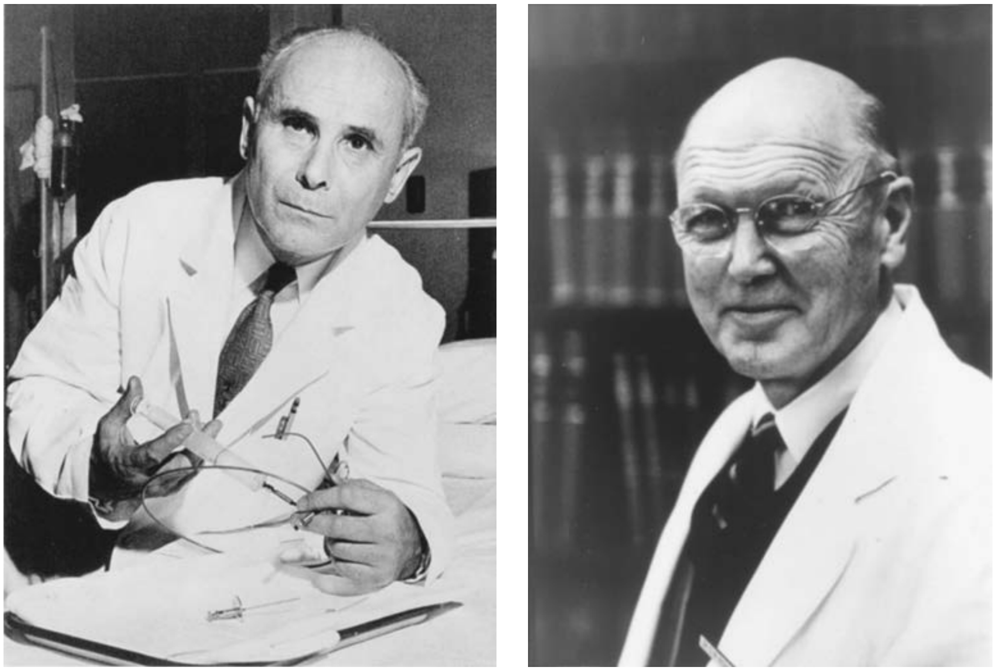

Figure 1-17 André Frederic Cournand (1895–1988) and Dickinson W. Richards (1895–1973). After Forssman's report of the uneventful catheterization of his own right heart, Cournand and Richards pioneered the use of cardiac catheterization for the study of the normal and the abnormal pulmonary circulation and the standardization of pulmonary function tests.

plague in Bombay—Koch maintained his interest in tuberculosis. This interest, however, led him into a major mistake—advocacy of tuberculin as a vaccine instead of as a diagnostic test. In 1905, he was awarded the Nobel Prize. On April 7, 1910, the year of his death, he delivered a final address on the epidemiology of tuberculosis before the Berlin Academy of Sciences.

■ Physiology of the Pulmonary Circulation

Starting with William Harvey,[5] studies of the pulmonary circulation have gone hand in hand with advances in pulmonary physiology and medicine. For many years, research on the pulmonary circulation was confined to animal experimentation. A giant step forward was made with the introduction of cardiac catheterization in humans.

Accurate measurement of pulmonary blood flow is a sine qua non for assessing pulmonary and cardiac performance in health and disease. The use of nitrous oxide in humans by Krogh and Lindhard was an important beginning in this direction, but not until mixed venous blood could be sampled for application of the Fick principle could reliable determinations of pulmonary blood flow be made.

Claude Bernard in 1846, and Chauveau and Marey in 1861, had catheterized the right side of the heart in animal experiments. Whether this technique could be used safely in humans was not known until 1929, when Werner Forssmann, a young surgeon in Germany, introduced a ureteral catheter into his own right atrium. In the 1940s, Cournand, Richards, and their colleagues resorted to right heart catheterization to obtain mixed venous blood for the determination of cardiac output by application of the Fick principle (Fig. 1-17). The technique opened the way not only to the accurate determination of cardiac output, but also to exploration of the heart and lungs in a wide variety of clinical disorders.

Until 1946, when von Euler and Liljestrand reported the effects of hypoxia and hypercapnia on the pulmonary circulation in an open-chest preparation of an anesthetized cat (Fig. 1-18),[36] there was little understanding of the regulation of the pulmonary circulation. However, these studies, coupled with the proposition of local control of the pulmonary circulation by local concentrations of the respiratory gases, paved the way to understanding pulmonary hypertension and the behavior of the pulmonary circulation in normal individuals at rest, after birth, during exercise, and at altitude, and in individuals with heart or lung disease.

The interposition of the pulmonary circulation between the right and left sides of the heart is a prerequisite for gas exchange. However, it also serves a variety of other functions, for example, a mechanical role, as a filter for particulate matter in blood returning to the heart, and a metabolic role, effecting the synthesis, uptake, and breakdown of biologic compounds. Extensive studies have been

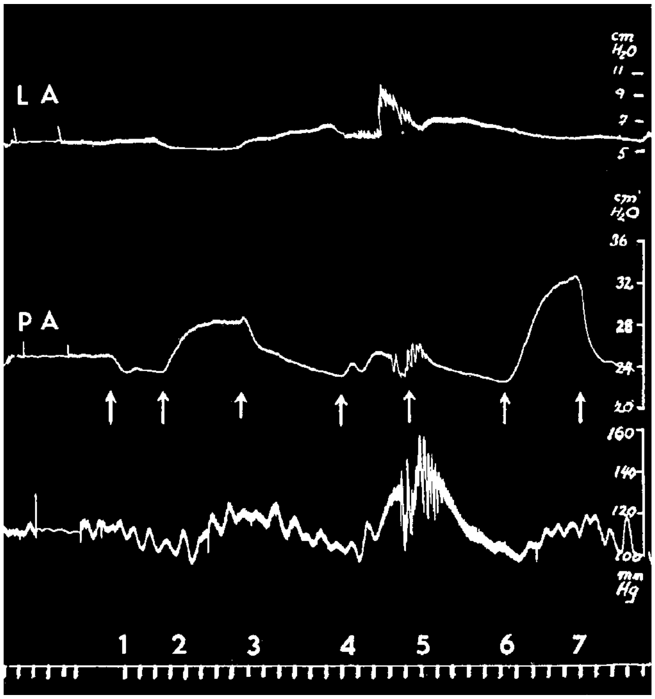

Figure 1-18 Effects of the blood gases on pulmonary arterial pressure in the open-chest cat, artificial respiration. LA, left atrial pressure; PA, pulmonary arterial pressure; lower trace, systemic arterial blood pressure. Numbers along the baseline represent the administration of test gases: 1, O_2 (from air); 2, 6.5% CO_2 in O_2; 3, O_2; 4, 18.7% CO_2 in CO_2; 5, O_2; 6, 10.5% O_2 in N_2; 7, O_2. *(Reproduced with permission from Von Euler US, Liljestrand, G: Observations on the pulmonary arterial blood pressure in the cat. Acta Physiol Scand. 1946;12(4):301–320.)*

conducted in recent decades on the nonrespiratory functions of the lungs. From these studies has emerged considerable understanding of the diverse functions served by the branching pulmonary circulation and its components, including the endothelium and smooth muscle and their interplay.

TECHNOLOGIC ADVANCES THROUGH THE EARLY 20TH CENTURY

The road to contemporary pulmonary medicine could be just as easily traced by using technologic advances as landmarks, instead of people and discoveries. For example, the introduction of the manometer for pressure recording, the use of chambers to simulate high altitude, the development of accurate blood gas analyzers, and the application of sophisticated optical systems for viewing the lumens of the airways and the inside of the chest cavity are all notable milestones. However, probably no better example exists than the discovery of radiographs and the application of this discovery to the diagnosis, prevention, and management of pulmonary tuberculosis.

Wilhelm Conrad Roentgen discovered radiographs in 1895 while experimenting with cathode ray tubes in his physics laboratory at the University of Wurzburg. Although others before him had seen radiographs as early as 1890, Roentgen was apparently the first to grasp the full significance of the discovery, and his publication, quite unpretentious, immediately attracted worldwide attention because of its prospects for the study of anatomic structures and pathologic changes.

Within 2 years after Roentgen's discovery, fluoroscopy of the chest had been introduced into clinical practice, and its value in the early detection of tuberculosis and the diagnosis of pleural effusions was appreciated. In 1901, an atlas of chest radiographs was published, and the use of chest radiography increased greatly with each subsequent improvement in hot cathode radiograph tubes and intensifying screens. The radiographic evaluation of tuberculosis was superior to physical examination for diagnosis and characterization of the disease. By 1910, all patients admitted to sanatoriums had a chest radiographic examination, and by 1917 tuberculosis was classified according to radiographic findings.

MAJOR DEVELOPMENTS SINCE THE MID-20TH CENTURY

Many notable developments have occurred over the last 60 years in pulmonary medicine and the related field of critical care. Measured against the metric of having a broad and deep impact on clinical care, several are particularly noteworthy: advances in thoracic imaging, lung transplantation, bronchoscopy and interventional bronchoscopic techniques, and advances in management of the critically ill, including those infected with COVID-19 (SARS-CoV-2).

Advances in Thoracic Imaging

Following Roentgen's discovery of the x-ray at the turn of the 20th century, another major diagnostic leap forward in pulmonary medicine occurred with development of computerized tomography (CT) in the 1960s.[37–39] In 1967, the first experimental CT scan was generated, with computer reconstruction of an image of a mouse taking 9 days to complete. The first human application was a head CT that demonstrated a brain tumor (Fig. 1-19). In 1973, Dr. Godfrey Hounsfield published a description of CT scanning in the British Journal of Medicine. Along with Dr. Allan Cormack, Hounsfield (Fig. 1-20) was awarded a Nobel Prize in 1979.

Application of CT to lung imaging arose in the mid-1970s; high-resolution techniques were developed in the 1980s. Multi-slice CT scanning now permits rapid acquisition of high-resolution images from which multiplanar reconstructions can be derived (Fig. 1-21). Elegant characterization and classification of a variety of interstitial and airway diseases is now possible using CT. In addition, when coupled with intravenous contrast injection (CT angiography),

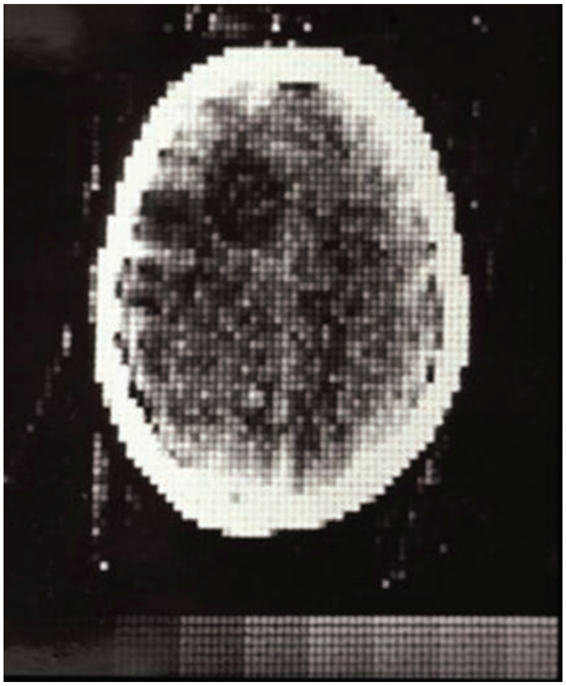

Figure 1-19 The first clinical CT scan, obtained in 1971. The grainy image shows a brain tumor in a frontal lobe (*left side* of image). Advances in image quality over the last four decades have been dramatic. *(Reproduced with permission from impactscan.org.)*

Mortani Barbosa, Jr.)*

rapid, high-resolution scanners provide for the very accurate diagnosis of pulmonary embolism[40] and other pulmonary vascular disorders. Advances in multi-slice techniques (e.g., 320-slice scanners) offer extremely high-quality imaging.

Aligning the anatomic detail provided by CT with functional images afforded by positron emission tomography (PET) has generated useful information on the staging and clinical assessment of bronchogenic carcinoma, particularly non–small-cell carcinoma.[41–45] Positively charged electrons (positrons), emitted from injected radionuclides, are destroyed by electrons and, in the process, produce photons that are detected and imaged by the PET scanner. Malignant cells, by virtue of having increased numbers of cell membrane–based glucose transporters compared with normal cells, accumulate greater levels of the radionuclide, ^{18}F-fluorodeoxyglucose (F-FDG), which cannot be metabolized further and is trapped within the cells. The tracer-enriched collection of malignant cells stands out against the background of normal tissue. Coupling of the PET-based and CT images provides precise localization of the area of abnormality (Fig. 1-22). PET/CT imaging has been used to evaluate solitary pulmonary nodules, assess local extent of disease (particularly mediastinal and pleural involvement) in lung cancer, and evaluate distant anatomic sites for metastatic disease.

■ Lung Transplantation

Following on the heels of pioneering animal experimentation conducted by Vladimir Demikhov,[46] the first reported human lung transplantation was conducted by Dr. James Hardy and colleagues in 1963.[47,48] However, it was not until the 1980s that clinically meaningful outcomes were achieved by Dr. Joel Cooper and colleagues with single-lung[49] and bilateral-lung[50] transplantation.

Since the advent of lung transplantation, approximately 70,000 procedures have been performed worldwide. Survival of recipients has improved from 4.0 years in the late 1980s and early 1990s to 5.8 years in the last decade. Contemporary, overall survival rates are 85% at 1 year and 59% at 5 years.[51,52] Lung transplantation is associated with improvements in lung function, exercise tolerance, and hemodynamic parameters. Currently, the primary diagnoses for which lung transplantation is most commonly conducted include idiopathic pulmonary fibrosis (IPF), chronic obstructive pulmonary disease (COPD), cystic fibrosis (CF), and other disorders, including alpha-1-antitrypsin deficiency, sarcoidosis, non-CF bronchiectasis, lymphangioleiomyomatosis (LAM), and primary pulmonary hypertension.[53,54]

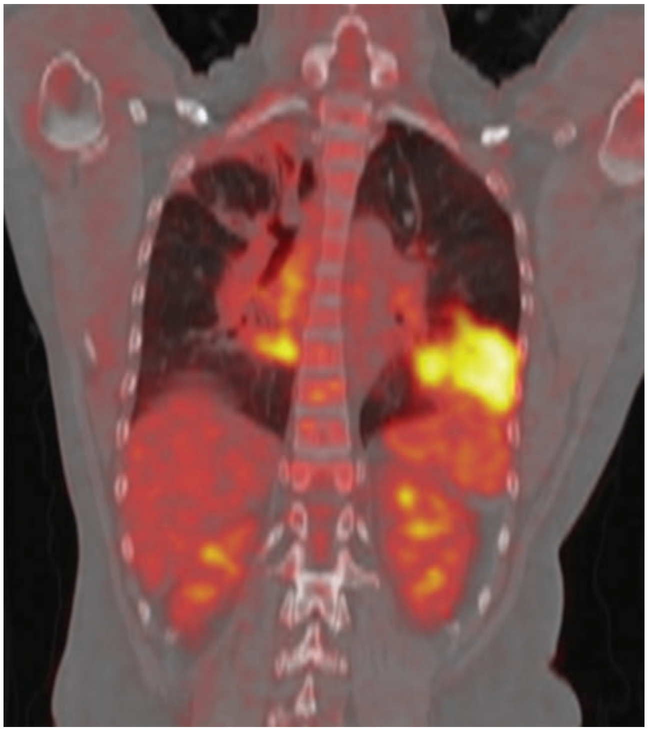

Figure 1-22 A coronal PET/CT image demonstrating metastatic lung cancer, evident as bright areas (in *yellow*) at the left base and the right hilum. The PET and CT images are aligned ("in register") to create precise anatomic localization of the heightened metabolic activity noted in the PET image. *(Reproduced with permission from Dr. Eduardo J. Mortani Barbosa, Jr.)*

Despite tremendous advances in the field, complications of lung transplantation are common and include primary graft dysfunction (noncardiogenic pulmonary edema without other apparent cause occurring in the first 72 hours following transplantation); bronchial stenosis developing at the anastomotic site; a broad array of infectious complications, including CMV infection; acute rejection (occurring in over one-third of recipients); and chronic allograft dysfunction due to bronchiolitis obliterans.[53]

Improved surgical techniques in lung transplantation have been important. However, critical to advances in solid organ transplantation, including lung transplantation, has been development of effective immunosuppressive regimens. The earliest regimens included a limited repertoire of drugs, for example, corticosteroids and azathioprine. Development of calcineurin inhibitors, including cyclosporine in 1977 and tacrolimus in 1983, substantially advanced the field.[55]

While technical and pharmacologic advances in lung transplantation afford many patients with advanced lung disease improved quality of life, a limited supply of suitable donor organs persists. Various approaches have been employed in an attempt to ameliorate the continuous shortage. In addition to obtaining organs from brain-dead donors as the primary source, more recently, many transplant programs have embarked on the somewhat controversial program of donation after cardiac death (DCD) or donation from "non–heart-beating donors," who undergo controlled withdrawal of life support in an operating room. In addition, new technologic developments in organ "reconditioning" offer hope for enlarging the supply of transplantable lungs.[56–58]

Figure 1-23 Gustav Killian (1860–1921), the father of bronchoscopy. *(Reproduced with permission from Klaus D. Peter, Wiehl, Germany. Released to the public domain, via Wikimedia Commons.)*

Bronchoscopy and Interventional Bronchoscopic Techniques

Application of bronchoscopic techniques, both rigid and flexible, has revolutionized the field of pulmonary medicine, from both diagnostic and interventional perspectives. Credit for invention of the rigid bronchoscope is given to Gustav Killian (Fig. 1-23) in Germany in the late 19th century;[59] in the United States, the field of rigid bronchoscopy was pioneered by Chevalier Jackson in Philadelphia (Fig. 1-24).[60] The next major wave in bronchoscopy arose with development of the flexible fiberoptic technique by Shigeto Ikeda in Japan.[61,62] Since then, significant advances in optics, digital technology, and a variety of interventional techniques, including those based on the fiberoptic method, have been reported.

Advances in Critical Care

In parallel with the previously noted advances in imaging, transplantation, and bronchoscopy, significant progress in the management of critically ill patients has occurred over the last several decades. One of the most notable is application of mechanical ventilation.[63–65]

The era of the "iron lung," the first widely used negative pressure ventilator, dates back to 1928 (Fig. 1-25).[66–68] Restricted access to the patient was a major limitation to use of the device. The advent of positive pressure ventilators, dramatically evident during the polio epidemic in Copenhagen in 1952, ushered in the "modern" era of mechanical ventilation.[69] Indeed, the clustering of paralyzed patients needing ventilatory support paved the way for development of medical intensive care units. Subsequent invention of the Bennett valve, a result of efforts to establish a means of facilitating high-altitude flight for military purposes, further enhanced clinical use of positive pressure ventilation.[70–73] Many additional refinements in mechanical ventilation, including microprocessor-controlled functions, have evolved over the last quarter century. One noteworthy development in the field deserves special consideration: use of the "low-stretch protocol."

Based on recognition that application of traditionally used tidal volumes of 10 to 15 mL/kg body weight may cause stretch-induced injury in patients with acute lung injury (ALI) and acute respiratory distress syndrome (ARDS), a multicenter prospective trial was undertaken to address whether use of smaller tidal volumes (6 mL/kg), that is, a "low-stretch protocol," would improve outcomes. Indeed, in a landmark study published in 2000, an approximate 25% reduction in mortality using a low-stretch protocol was demonstrated.[74] Additional refinements, including use of higher levels of positive end-expiratory pressure (PEEP)[75] and the so-called "lung recruitment maneuvers"[76] have been added to the contemporary ventilator management scheme for these patients.

In addition to advances in mechanical ventilation, other notable recent refinements in critical care include recognition of the value of venous thromboembolism prophylaxis, prophylaxis against gastrointestinal bleeding, semierect patient positioning to minimize aspiration risk, good (but not excessive) glycemic control, application of spontaneous breathing trials and sedation interruption, and early patient mobilization. However, one particular development warrants special mention: use of early goal-directed therapy (EGDT) in sepsis.

Sepsis is a severe, systemic response to infection and is associated with high mortality. A reflection of the systemic inflammatory response syndrome (SIRS), sepsis may progress to severe sepsis (end-organ dysfunction in the setting of documented or suspected infection) or septic shock (severe sepsis with hypotension unresponsive to intravenous fluid administration). An important study published in 2000 addressed the value of EGDT in the management of septic patients. Such therapy focuses on early and aggressive fluid administration titrated to a goal central venous pressure (CVP), mean arterial blood pressure (MAP), and target central venous oxygen saturation (Scv_{O2}), and incorporates use of vasoactive agents and transfusion of packed red blood cells as necessary. Application of EGDT has been shown to reduce mortality by as much as one-third[77] and constitutes one of the cornerstones of management of critically ill patients with sepsis, as comprehensively discussed in the "Surviving Sepsis Campaign Guidelines for Management of Severe Sepsis and Septic Shock."[78]

Acute Lung Injury Related to COVID-19

In late 2019, a cluster of cases of pneumonia due to a novel coronavirus emanating from Wuhan, China, was reported.[79] The World Health Organization designated the disease as COVID-19, the causative organism of which is SARS-CoV-2 (Fig. 1-26). We now know that the major morbidity and mortality due to this infection is acute viral pneumonia that may evolve to ARDS.[80,81]

The pandemic has stimulated rapid evaluation of a variety of modalities related to management of the critically ill patient with diffuse lung injury, including prone positioning,[82,83] use of high-flow oxygen therapy and noninvasive mechanical ventilation prior to consideration of intubation, use of adjunctive agents, including corticosteroids,[84] and an alternative to a low-stretch ventilator protocol, based on data suggesting that the disturbed lung mechanics in COVID-19-related ARDS are different from those of other causes of ARDS.[85,86]

The social and economic consequences of COVID-19 pandemic have been extraordinary. With well over 250 million infections and more than 5 million deaths worldwide, the impact of the pandemic has triggered debate over the preparedness of nations globally for dealing with future pandemics. As the world struggles with containing COVID-19, attention has been intensely focused on development of effective vaccines and therapeutics.

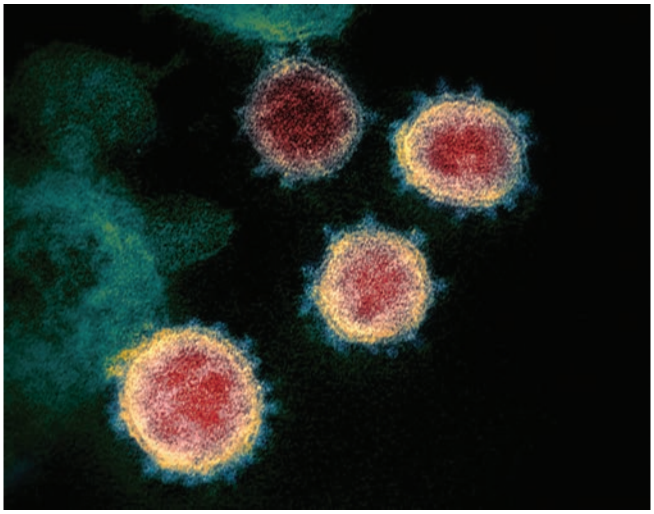

Figure 1-26 Transmission electron microscope image of SARS-CoV-2, the virus that causes COVID-19. The image shows virus particles emerging from laboratory-cultured cells. Spikes on the surface of the virus, appearing as a crown, account for the name, "coronavirus." *(Reproduced with permission from NIH Research Matters: Novel coronavirus structure reveals targets for vaccines and treatments. CHAPTER 2

Functional Design of the Human Lung for Gas Exchange*

Matthias Ochs

INTRODUCTION

At the end of a deep breath, about 80% of the lung volume is air, 10% is blood, and only the remaining 10% is tissue. Because this small mass of tissue is spread over an enormous area—nearly the size of a tennis court—the tissue framework of the lung must be extraordinarily delicate. It is indeed remarkable that the substance of the lung manages to maintain its integrity in the face of the multitude of insults that inevitably accompany a lifetime of exposure to ambient air and the complex necessity of keeping air and blood in intimate contact, but separate, for the sake of gas exchange.

Part of this success is undoubtedly attributable to the unique design of the lung, which ensures mechanical stability as well as nearly optimal conditions for the performance of the lung's primary function: to supply the blood with an adequate amount of oxygen even when the body's demands for oxygen are particularly high, as during heavy work.

THE LUNG AS AN ORGAN

At total lung capacity, the lung fills the entire chest cavity and can reach a volume, in the adult human, of some 5 to 6 L, largely depending on body size. Upon expiration, the lung retracts, most conspicuously from the lower parts of the pleural cavity, the posterior bottom edge of the lung moving upward by some 4 to 6 cm. This preferential lifting of the bottom edge is caused by retraction of the tissue throughout the entire lung, the surfaces of which are freely movable within the thoracic cavity.

The structural background for this mobility of a healthy lung is the formation, during morphogenesis, of a serosal space that is lined on the interior of the chest wall and on the lung surface by a serosa, the parietal and visceral pleurae, respectively (Fig. 2-1). However, this serosal space is minimal, since the visceral pleura is closely apposed to the parietal pleura, with only a thin film of serous fluid intercalated as a lubricant between the two surfaces.[1] Both pleural surfaces are lined by a squamous epithelial layer, often called *mesothelium* (due to its mesodermal origin), whose surface is richly endowed with long microvilli. The apical microvilli increase the surface area available, suggesting that pleural mesothelial cells are capable of participating in active transserosal transport of solutes. The total volume of pleural fluid is about 15 to 20 mL, with approximately 1700 cells/mm^3 (75% macrophages, 23% lymphocytes, 1% mesothelial cells). The volume and composition of the pleural fluid have to be tightly controlled to ensure an efficient mechanical coupling between chest wall and lung. Pleural fluid originates from pleural capillaries through microvascular filtration. Drainage occurs partly via lymphatic stomata in the parietal pleura. Transcytosis through mesothelial cells in both directions represents another mechanism involved in pleural fluid homeostasis.[2–6]

The connective tissue of the visceral pleura consists of three layers. A superficial layer of predominantly elastic fibers follows the mesothelium, thereby forming an elastic "bag" that enwraps each lobe. A deep sheet of fine fibers follows the outline of alveoli and extends into the depth of the lung. Between these sheets lies a bed of loose connective tissue, containing free cells (histiocytes, plasma cells, and mast cells), that is often close to lymphatics and systemic arterial branches from the bronchial arteries.

The lung is maintained in a stable position within the chest by the hilum, where airways and blood vessels enter from the mediastinum, and by the pulmonary ligament, a long, narrow band of attachment between visceral and mediastinal pleura that extends downward from the hilum. Because of these attachments, a pneumothorax causes the lung to retract and form a lump of tissue that is attached to the mediastinal wall of the thoracic cavity.

The shape of the lung is congruent with that of the fully expanded pleural cavity. This shape is preformed in lung tissue and is hence also evident if an excised lung is inflated, revealing its three faces: the convex thoracic face apposed to the rib cage, the concave diaphragmatic face modeled by the diaphragmatic dome, and the mediastinal face, on which the contours of the heart are impressed beneath the hilum.

As the lung retracts during deflation, the acute edges between the thoracic face and the diaphragmatic and (anterior) mediastinal faces of the lung withdraw; the thoracic and diaphragmatic leaflets

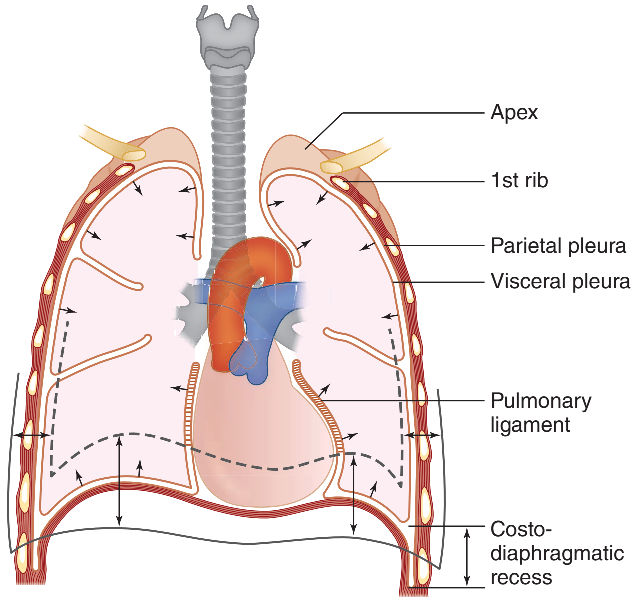

Figure 2-1 Frontal section of chest and lung showing pleural space. *Single arrows* indicate retractive force. *Double arrows* show the excursion of the lung bases and periphery between deep inspiration and expiration.

---

*The author would like to acknowledge the major contribution of Ewald R. Weibel (1929–2019) to previous versions of this chapter.

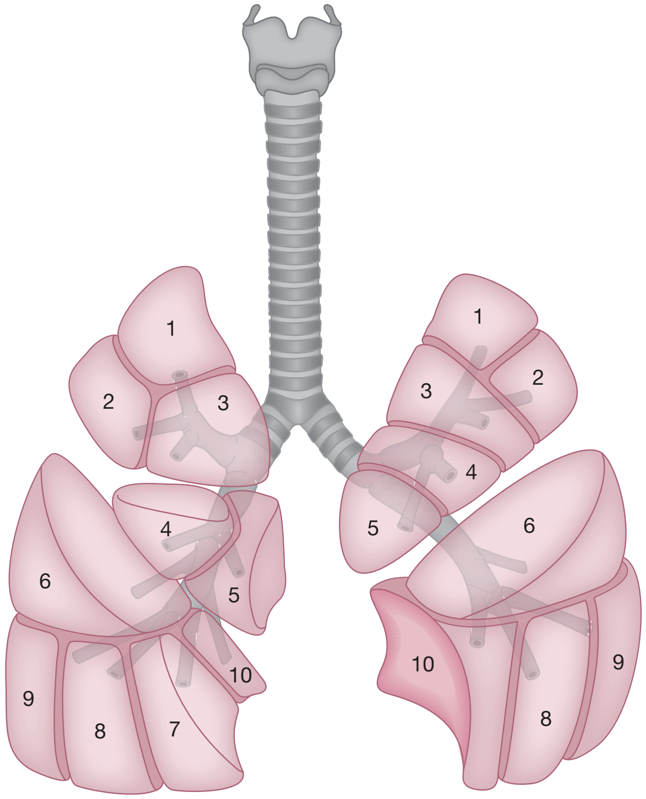

Figure 2-2 Bronchopulmonary segments of human lung. Left and right upper lobes: (1) apical, (2) posterior, (3) anterior, (4) superior lingular, and (5) inferior lingular segments. Right middle lobe: (4) lateral and (5) medial segments. Lower lobes (6): superior (apical), (7) medial–basal, (8) anterior–basal, (9) lateral–basal, and (10) posterior–basal segments. The medial–basal segment (7) is absent in the left lung. (Note: The lungs are represented as turned inward slightly to display part of the lateral face.)

of the parietal pleura become apposed, thereby forming a costodiaphragmatic recess on each side (Fig. 2-1). Similarly, as the ventral edge of the lung retracts, the costal and mediastinal pleurae form a recess on each side, corresponding topographically to the borders of the sternum.

The port through which airways and blood vessels enter the lung is the hilum, that is, the attachment of lung tissue to the mediastinum (Fig. 2-1). The airways reach the two hili by the mainstem, or principal, bronchi (Figs. 2-1 and 2-2). The left mainstem bronchus is longer than the right because it must pass under the aortic arch before it reaches the lung. The two principal bronchi course downward and begin to divide sequentially shortly after entering the lung, first releasing the lobar bronchus to the upper lobe (Fig. 2-2). Since a middle lobe is formed only on the right side, there is no middle lobe bronchus on the left; instead, the corresponding parts form the lingula, which receives its airways from the superior bronchus of the upper lobe (Fig. 2-2). The last branch of the stem bronchus goes to the lower lobe.

The branching pattern of the human bronchial tree and of the pulmonary artery and veins are shown in a resin cast in Fig. 2-3. The pulmonary artery joins the bronchi while still in the mediastinum (Fig. 2-4A); its trunk lies to the left of the ascending aorta, and the right pulmonary artery turns dorsally to course between ascending aorta and right principal bronchus. In the hilum, the right pulmonary artery lies anterior to the right principal bronchus; the left pulmonary artery, however, "rides" on the principal bronchus and crosses over the superior lobar bronchus to the posterior side. From there on, the pulmonary artery branches in parallel with the bronchi; characteristically, each bronchus is associated with one closely apposed pulmonary artery branch, and this relationship is strictly maintained to the periphery, that is to the respiratory bronchioles.

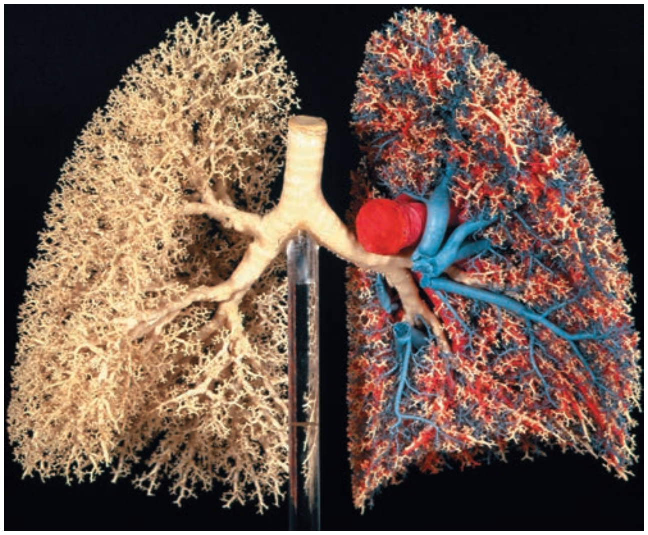

Figure 2-3 A resin cast of the human airway tree shows the dichotomous branching of the bronchi from the trachea and the systematic reduction of airway diameter and length with progressive branching. In the left lung the pulmonary arteries *(red)* and veins *(blue)* also are shown.

In contrast, the pulmonary veins (Fig. 2-4B) follow a course independent of the bronchial tree; rather, they lie about midway between two pairs of bronchi and arteries; this position is maintained to the periphery of the airway system. In the hilum, these veins are collected into at least two main veins on either side, which lead into the left atrium located at the back of the heart.

The airways systematically branch over an average of 23 generations of dichotomous branching,[7,8] ending eventually in a blind sac (Fig. 2-5). The last nine generations of these airways are connected to tightly packed alveoli, airway chambers in which gas exchange takes place, whereas the central airways serve the function of conducting the air to the gas-exchange parenchyma. In such a system of sequential branching, the unit of lung parenchyma could be defined according to the portion of parenchyma that is supplied by a particular branch of the bronchial tree, and it is possible to conceive of as many types of units as there are generations unless clear definitions for such units are proposed. However, two units appear to be natural:

1. The lobes, which are demarcated by a more or less complete lining of pleura. There are three lobes on the right (superior, middle, and inferior lobes), and two on the left (superior and inferior lobes).
2. The acinus, which is defined as the parenchymal unit in which all airways have alveoli attached to their wall and thus participate in gas exchange. Along the airway tree, the acinus begins with a transitional bronchiole (Fig. 2-5).[9,10]

Since all other units are somewhat arbitrarily defined, it is not surprising that some ambiguity exists in the literature about their meanings. Nonetheless, a certain convention has been adopted with respect to the following:

1. The lung segments, which are considered as the first subdivisions of lobes. Figure 2-2 shows the location and distribution of the segments to the various lobes. The symmetry is imperfect because on the left the two segments corresponding to the right middle lobe are incorporated into the superior lobe as the lingula (segments 4 and 5) and because the medial–basal segment of the lower lobe is generally missing on the left (segment 7).

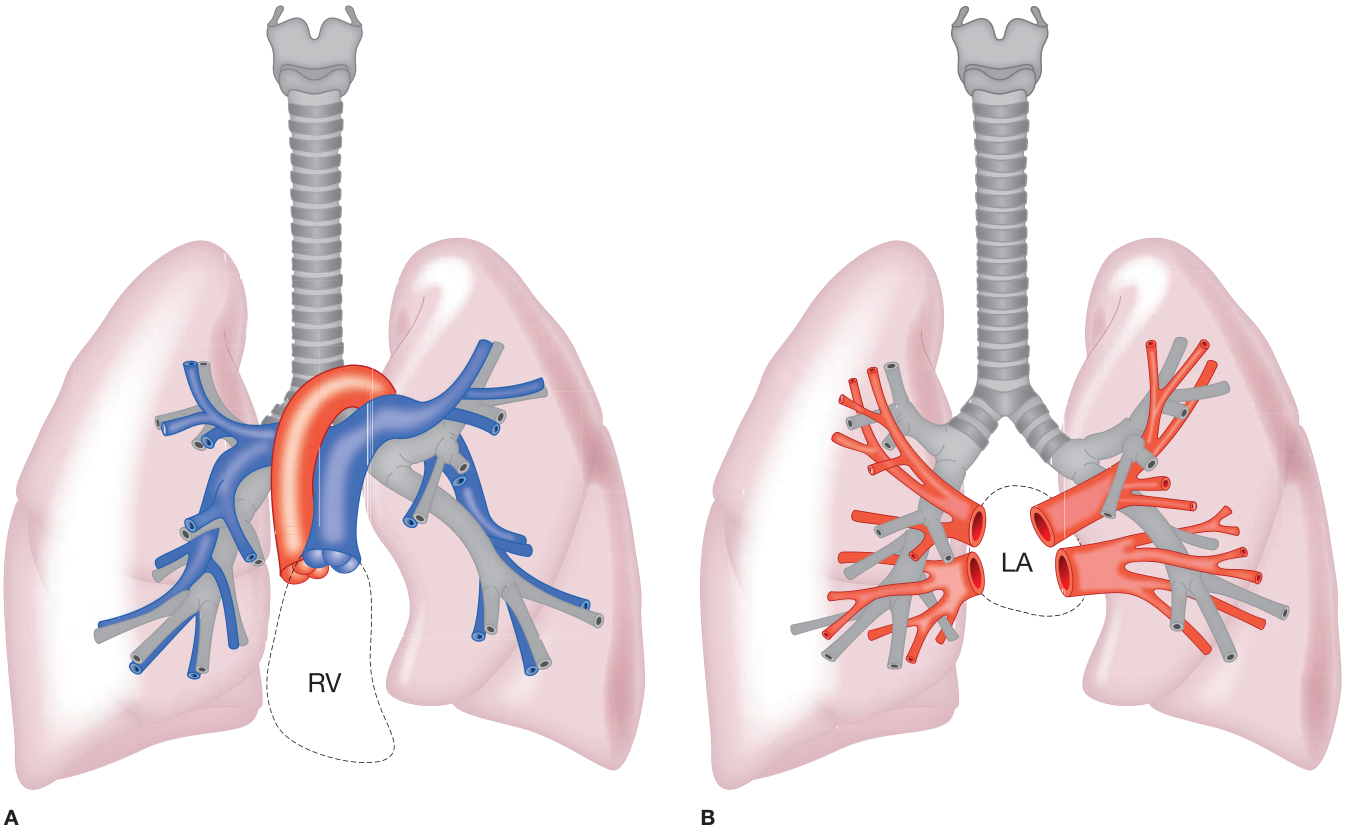

Figure 2-4 Schematic diagrams of the relation of the main branches of pulmonary arteries (**A**) and pulmonary veins (**B**) to the bronchial tree. The arteries follow the airways. Two mainstems of pulmonary vein penetrate independently into the lung on each side. LA, left atrium; RV, right ventricle.

2. The secondary lobule, an old anatomic unit. It was introduced in the 19th century because "lobules" of about 1 cm^3 are visible on the surface of the lung. These lobules are delineated by connective tissue septa that are connected to the pleura. The secondary lobule is difficult to define in terms of the bronchial tree, but it does seem to comprise about a dozen acini. With reference to radiologic imaging techniques, secondary lobules are supplied by airway branches that are about 1 mm in diameter.

The pulmonary blood vessels show a characteristic relationship to these units (Figs. 2-3 and 2-4). The pulmonary arteries, following the airways, course through the centers of the units and finally fan out into the capillaries located in the delicate alveolar septa of lung parenchyma. In contrast, the veins lie in the boundary between units and collect the blood from at least two or three adjacent units. This arrangement applies to acini and secondary lobules as well as to lung segments.

Therefore, it is evident that the units of lung parenchyma are bronchoarterial units, which share their venous drainage with neighboring units. This architecture has important functional and practical consequences. Except for the lobes, none of the units is separated from each other by complete connective tissue septa.

ORGANIZATION OF LUNG TISSUE

Lung tissue is a complex structure. Its individual components are discussed below.

Basic Structural Elements

While looking at the tissue organization of the lung, we must first consider that the airways and the blood vessels each have their own lining by an uninterrupted cell layer. These layers extend all the way out to the gas-exchange region, but they show different properties in conducting as compared with respiratory structures. Likewise, the connective tissue forms a continuum throughout the lung all the way out to the pleura, but it, too, will be differently organized in the different functional zones; whereas it is reduced to a minimum in the alveolar walls, it contributes a number of different ancillary structures to the wall of conducting airways and blood vessels, such as smooth muscle sheaths or cartilage. This connective tissue space also houses the nutritive vessels and nerves as well as the elaborate defense system related to lymphatic vessels. In the gas-exchange region, however, very few of these accessory structures are found.

The complexity of lung structure is also reflected at the cell biologic level. There is no such thing as a standard "lung cell." Instead, based on morphologic criteria, some 40 different cell types, which are highly specialized, both structurally and functionally, can be found in the lung.[11–13]

A word of caution is also necessary with respect to the extrapolation of structural findings in experimental animals, especially rodents, to the human lung. Noteworthy species differences include the bronchial circulation, the presence of respiratory bronchioles, the ultrastructural composition and distribution of nonciliated bronchiolar epithelial cells (club cells) and their protein expression pattern, the frequency of certain cell types like alveolar brush cells and lipid-containing interstitial cells (lipofibroblasts), and the ultrastructural organization of lamellar bodies in type II alveolar epithelial cells. All these structural elements have features characteristic of the human lung that are not found in rodents.[14]

Wall Structure of Conducting Airways

The wall of conducting airways consists of three major components (Figs. 2-6 and 2-7): (1) a mucosa composed of an epithelial and a connective tissue lamina; (2) a smooth muscle sleeve; and (3) an enveloping connective tissue tube partly provided with cartilage.[15]

Figure 2-5 Model of airway branching in human lung by regularized dichotomy from trachea (generation z = 0) to alveolar ducts and sacs (generations 19–23). The first 14 generations are purely conducting; transitional airways (generation 15) lead into the acinar airways with alveoli that branch over 8 generations (z′). *(Modified with permission from Weibel ER: Morphometry of the Human Lung. Heidelberg: Springer-Verlag; 1963.)*

Epithelium

Although derived from the same anlage,[16,17] the airway epithelium modifies its differentiation characteristics as we proceed from large bronchi over bronchioles to the alveolar region (Fig. 2-6). A simple epithelium exists as a lining of smaller bronchioles: As we move upward toward larger bronchi, the epithelium becomes higher and some basal cells appear, making the epithelium pseudostratified. At the point of transition into the gas-exchange region—that is, at the entrance into the complex of alveoli—the epithelium abruptly becomes extremely thin. Figure 2-6 also shows that the epithelium is not made of a uniform cell population but that it is, at each level, rather a mosaic of at least two cell types, in that secretory cells as well as some rarer special cells are interspersed into the complex of lining cells.[15,18]

If we first have a closer look at the epithelium of larger conducting airways, we see that the lining cells are provided with a tuft of kinocilia at their apical cell face, whereas the secretory cells are goblet cells that produce and discharge to the surface a sticky mucus (Figs. 2-7–2-9). This mucus spreads out as a thin blanket on top of the cilia, which are embedded in a periciliary layer containing a dense network of mucins and mucopolysaccharides tethered to the cilia.[19] The mucus layer is capable of trapping dust particles that are still contained in the air entering the lung. Kinocilia (Fig. 2-10) are motile cell extensions that are known to beat rhythmically in a given direction and at a frequency of about 12 to 20 Hz.[20,21] In the airway epithelium, the cilia are oriented in such a fashion that their beat is directed outward. It is interesting that the cilia of airway epithelia develop at their tip fine claws with which they can grasp the mucus blanket in the phase of their forward beat, whereas on their return to the upright position they glide past the mucus blanket. The result of this is that the mucus blanket, together with trapped foreign material, moves outward or "up the airways" in a steady stream, a feature appropriately called the *mucociliary escalator*. Since the lining by ciliated cells is uninterrupted from the bronchioles, up the bronchi, to the trachea, this mucociliary escalator ends at the larynx, so that the normal fate of bronchial mucus is to be steadily discharged into the pharynx, whence it is swallowed, usually unnoticed. Only when an excessive amount of mucus accumulates in the trachea or in larger bronchi do we have to assist the system by coughing.

Figure 2-6 Airway wall structure at the three principal levels. The epithelial layer gradually becomes reduced from pseudostratified to cuboidal and then to squamous but retains its organization as a mosaic of lining and secretory cells. The smooth muscle layer disappears in the alveoli. The fibrous layer contains cartilage only in bronchi and gradually becomes thinner as the alveolus is approached.

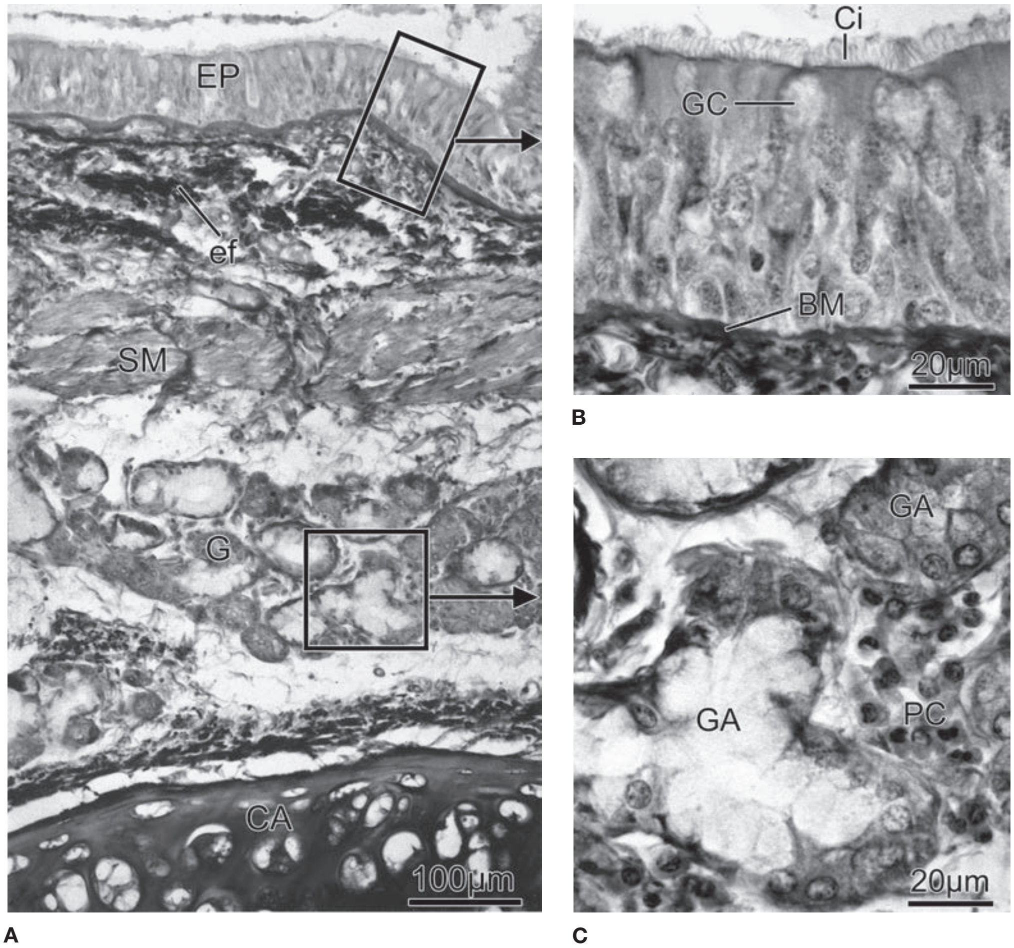

Figure 2-7 Light micrographs of bronchial wall. **A.** The layers from epithelium (EP) to cartilage (CA) with elastic fibers (ef), smooth muscle bundles (SM), and glands (G). **B.** Higher power of pseudostratified epithelium with cilia (Ci). **C.** Details of gland with acini (GA) associated with groups of plasma cells (PC). BM, basement membrane; GC, goblet cell.

The secretory cell population shows a number of specialized features. In the bronchi of all sizes and in larger bronchioles, one finds goblet cells interspersed between the ciliated cells; they form the mucus in their endoplasmic reticulum and Golgi complex, store it as droplets in their apical part, and discharge it in bulk (Figs. 2-8 and 2-9). In larger bronchi, one finds, in addition, small mucus glands located in the connective tissue; they are connected to the bronchial surface by long and narrow ducts (Figs. 2-6 and 2-7). In the normal bronchus, the glandular acini are relatively small and composed of serous and mucus cells; enlargement of the acini and a relative increase of mucus cells are characteristics of chronic bronchitis.

Finally, a special nonciliated secretory cell appears in the smaller bronchioles, the club cell (Fig. 2-11).[22,23] This cell population is very heterogeneous, thus displaying both interspecies and intraspecies variations.[24–28] In the human lung, club cells account for about 11%

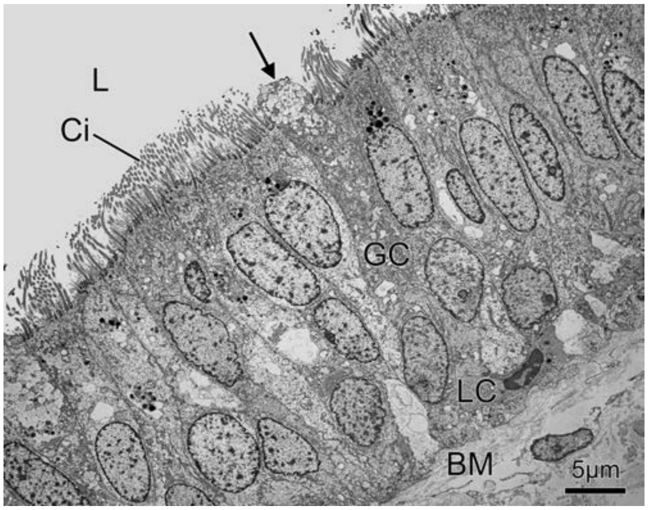

Figure 2-8 Electron micrograph of section across human bronchial epithelium made of high-columnar cells, most of which are ciliated (Ci). Figure 2-10 Cilia (Ci) from human bronchial epithelium seen on sections of epithelial cells in scanning electron micrograph (**A**), and on thin sections in longitudinal (**B**), and oblique cross section (**C**). They are implanted in the epithelial cell by a basal body (BB). Cross-sectioned cilium at high power (*inset*, **C**) reveals its membrane, which is enveloping a typical set of two axial tubules and nine peripheral duplex tubules with dynein arm (DY) attached. Note abundant short microvilli (MV) interspersed between cilia.

and 22% of the total epithelial cell number in terminal and respiratory bronchioles, respectively.[29] Besides the absence of cilia, club cells in conventional preparations are characterized by their dome-shaped apex that protrudes into the airway lumen. In contrast to that in rodents, where this cell is rich in smooth endoplasmic reticulum, club cells in the human lung lack significant amounts of smooth ER. They possess short lateral cytoplasmic extensions while their basal surface that rests on the basement membrane is practically free of infoldings. Membrane-bound electron-dense granules of about 500 to 600 nm diameter are present, which underlines their secretory activity. Our understanding of the functions of club cells is still incomplete. In many aspects, they appear to be functionally related to the secretory cell type of the alveoli, the type II alveolar epithelial cell; ultrastructural features and expression patterns of lung adenocarcinoma cells show characteristics of both club and type II cells. Club cell secretions add to the lining layer of the distal lung. Club cells synthesize and secrete the club cell secretory protein (CCSP),[22] which has been shown to be structurally similar to rabbit uteroglobin. The exact function of CCSP in the human lung still remains to be elucidated. CCSP levels in BAL fluid are decreased in smokers and in patients with COPD or interstitial lung diseases.[30] Animal studies suggest immunomodulatory functions for CCSP.[28] Within the lung, the club cell is the primary site of cytochrome P450 monooxygenase activity. Thus, they are heavily involved in detoxification of xenobiotics. Normal bronchiolar epithelial homeostasis is maintained by proliferation of club cells, whereas a cell population termed "variant Clara cells" or "variant CCSP-expressing cells," which is associated with neuroepithelial bodies or localized at bronchioloalveolar duct junctions, appears to act as progenitor cells for the bronchiolar epithelium under certain pathologic conditions.[28,31]

There are also some additional rarer cells. Neuroendocrine cells are capable of secreting mediators (amines and neuropeptides) into subepithelial capillaries. Prior to secretion, the bioactive substances are stored in dense-cored vesicles (Fig. 2-12). Occasionally, but only rarely in the adult human lung, these cells are organized in extensively innervated groups, and then termed "neuroepithelial bodies." Although it seems clear that neuroepithelial bodies have sensory, most likely oxygen-sensing, properties, their exact physiologic function is still poorly understood.[32–36] Another rare cell type of the airway epithelium is the brush cell (sometimes also referred to as "tuft cells"). These cells are characterized by the presence of an apical tuft of blunt, broad, and straight microvilli with root-like structures composed of filaments extending into the cytoplasm (Fig. 2-13). Glycogen granules, vesicles, and smooth endoplasmic reticulum are usually present as well. There is species variation in the occurrence of brush cells. While common in rodents (in rats even present in the proximal alveolar epithelium[37]) they are only rarely found in the human lung. Their function is only partly explored. Owing to their ultrastructure and their strategic localization in the airways and at alveolar duct bifurcations, sensory/chemoreceptor as well as sentinel/immune surveillance functions have been proposed.[38,39] Evidence suggests that brush cells "taste" the chemical composition of the airway lining fluid.[40,41] Based on single cell sequencing data, ionocytes have been identified as another rare cell type of the airway epithelium.[42,43] They express chloride channels, including cystic fibrosis transmembrane conductance regulator (CFTR).

Interstitium

The layer of connective tissue in the bronchial mucosa consists predominantly of elastic fibers that are oriented longitudinally;

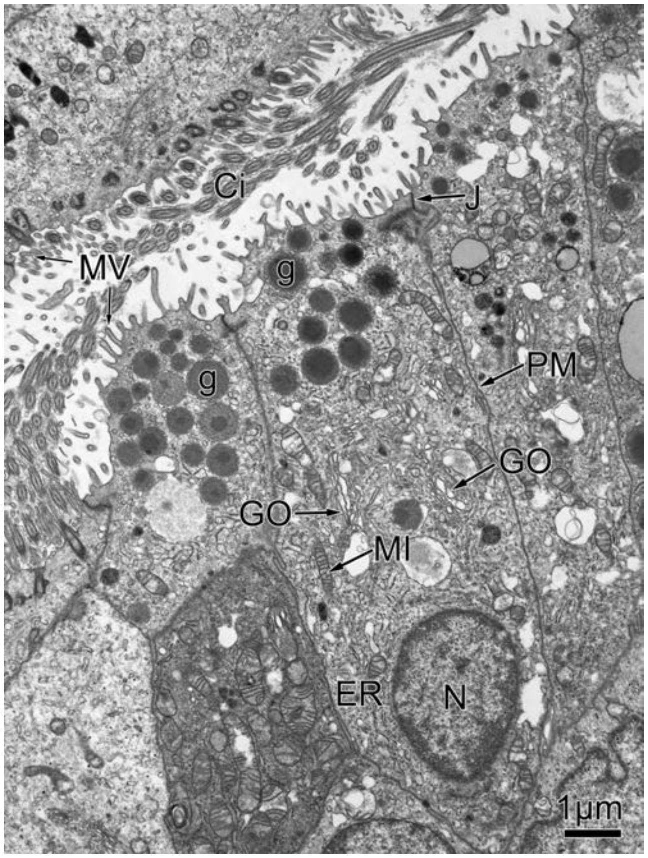

Figure 2-11 Club cells from human bronchiolar epithelium contain dense secretion granules (g) at apex. Note abundant cytoplasmic organelles such as mitochondria (MI), Golgi complex (GO), or endoplasmic reticulum (ER) as well as microvilli (MV) at surface. Cell membranes are closely apposed and form tight junctions (J) at apical edge. Ci, cilia; N, nucleus; PM, plasma membrane.

these fibers serve to maintain a smooth outline of the longitudinal profile of the bronchial lumen no matter how much the bronchi are stretched as the lungs are inflated. In this connective tissue lamina there are foci of lymphoid cells; often they form small lymphoid follicles.[44] However, bronchus-associated lymphoid tissue (BALT) is usually absent in normal adult human lungs and develops only after stimulation when inducible BALT might organize local immune responses.[45–48]

Smooth muscle bundles form a continuous sleeve in the connective tissue underlying the epithelial tube that extends from the major bronchi to the respiratory bronchioles; beyond the respiratory bronchioles, the bundles extend into the wall of alveolar ducts where the muscle fibers lie in the alveolar entrance rings. The bundles have an oblique course and encircle the mucosal tube in a crisscross pattern; hence, their contraction results primarily in a narrowing of the lumen.

In the small bronchioles there is little else to the airway wall; the smooth muscle layer is ensheathed by a layer of delicate connective tissue that is in direct contact with adjacent alveoli (Fig. 2-6). In the larger bronchioles and even more in the bronchi, the outer connective tissue sheath forms a strong layer of fibers; in the bronchi, rings or plates of cartilage are incorporated into this layer.

The wall structure in the respiratory bronchioles is identical to that of terminal bronchioles except that in some regions the cuboidal epithelium is replaced by an alveolar epithelium of squamous cells (type I cells) closely apposed to capillaries. Very often, these single alveoli constitute outpouchings in these regions; sometimes simple “respiratory patches” form in the bronchiolar wall (see below).

■ Wall Structure of Conducting Blood Vessels

The endothelial lining of pulmonary arteries and veins differs from that of capillaries by some site-specific structural and functional differences.[49–51] The endothelium of conducting blood vessels is thicker, and parts of its cytoplasm are richly endowed with organelles of various kinds (Fig. 2-14). Clearly, these cells are metabolically more active than those of the capillary endothelium. They are particularly rich in membrane-bound rod-shaped granules termed *Weibel–Palade bodies*,[52,53] which represent the regulated secretory organelles of endothelial cells (Fig. 2-14). The lumen of Weibel–Palade bodies

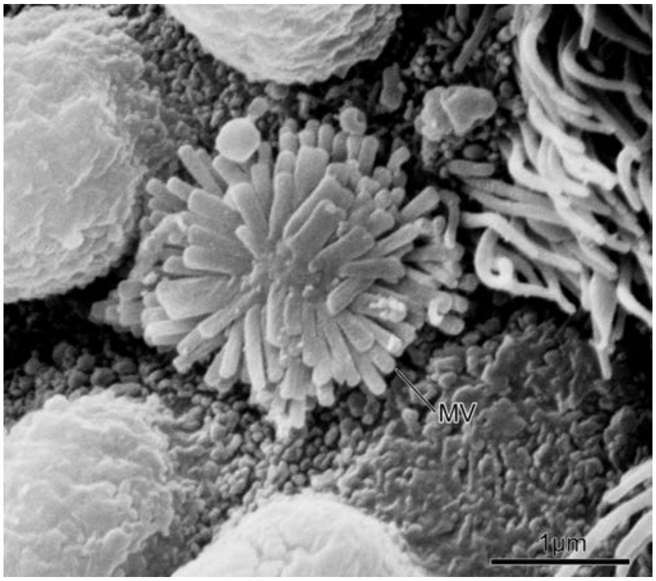

Figure 2-13 Brush cell from small bronchiole of rat lung containing broad microvilli (MV). *(Reproduced with permission from Fishman A, Fisher AB: Handbook of Physiology. Section 3: The Respiratory System. vol 1. Bethesda, MD: American Physiological Society; 1985.)*

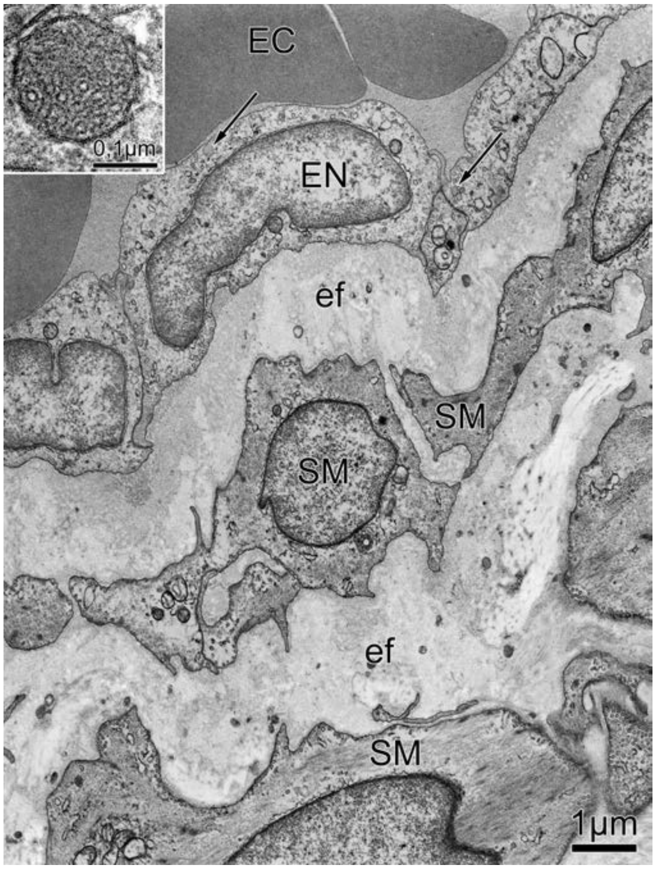

Figure 2-14 Part of wall of pulmonary artery from human lung. Endothelial cells (EN) form thick layer; their cytoplasm is rich in organelles. Specific granules of endothelium *(arrows),* a cross-section of one of which is shown at high power in the inset, are enveloped by a membrane and contain tubules. The arterial wall is of the elastic type, formed of alternating layers of smooth muscle (SM) and elastic fibers (ef). EC, erythrocyte.

is filled with longitudinally arranged tubules. These tubules represent von Willebrand factor,[54] packed in a highly organized spiral that allows rapid secretion into the blood. Other components of Weibel–Palade bodies include tissue-type plasminogen activator, endothelin 1, the leukocyte adhesion receptor P-selectin, interleukin 8, the tetraspanin CD63/LAMP-3, and the small GTPase Rab27a. Thus, Weibel–Palade bodies are actively involved in hemostasis as well as in vasoactive and inflammatory responses.[55–58]

Many of the nonrespiratory metabolic functions of the lung—particularly the transformation of certain bioactive substances, such as angiotensin and prostaglandins—are performed in endothelial cells. Caveolae (or plasmalemmal vesicles) have been implicated in these processes.[59,60] Caveolae are plasma membrane invaginations and associated vesicles with an outer diameter of about 50 to 70 nm. Depending on fixation, the shape of these invaginations appears omega- or cup-like.[61] Their structural framework consists of members of the caveolin family of proteins associated with cholesterol and sphingolipids. Caveolae perform transport and signaling functions and are involved in membrane organization. All endocytic activity mediated by caveolae (thereby bypassing the clathrin-coated vesicle pathway) is pooled under the term potocytosis.[62–65]

Accessory structures develop in the wall in accord with the functional properties of the vessels. Thus, the walls of the major pulmonary arteries that are close to the heart, and therefore exposed to the pressure oscillations of large amplitude prevailing in the outflow tract of the right ventricle, are of the elastic type—that is, layers of elastic lamellae are interconnected with smooth muscle cells as in the aorta; the tone of the smooth muscle regulates the elastic modulus of the vessel wall, thereby controlling the shape of the pulse wave. In the pulmonary arterial tree, this pattern prevails out to branches of about 1 mm diameter.

In contrast, branches less than 1 mm in diameter are of the muscular type, that is, the smooth muscle fibers encircle the vessel lumen; they can modify the vessel's cross-section and can thus regulate blood flow through this vessel. Compared with systemic arteries, the thickness of the pulmonary arterial wall is reduced about in proportion to systolic pressure, that is, by about a factor of 1:5; in pulmonary hypertension, the wall becomes thicker. Although arterioles are a well-defined entity in the systemic vascular bed, where they constitute the major site of arterial resistance, pulmonary arterioles are more difficult to locate and define. A single muscle layer—the histologic definition of an arteriole—does occur in branches about 100 µm in diameter, but the arterial bed continues out to the precapillaries, which consist of vessels 20 to 40 µm in diameter that are enwrapped by an incomplete smooth muscle sheath. This poverty of smooth muscle contributes importantly to the low resistance to blood flow that is normally afforded by the pulmonary arterial tree.

The structure of pulmonary veins is similar to that of systemic veins in the upper half of the organism. Their walls are rich in connective tissue and contain irregular bundles of smooth muscle. Larger veins contain a large amount of elastic tissue. More extensive in rodents, but to a certain degree also in humans, cardiac muscle tissue from the left atrial myocardium forms sleeves in the adventitia of pulmonary veins where they overlap with the smooth muscle of the venous wall. The arrangement of the myocardial sleeves correlates with the distribution of foci of ectopic beats initiating atrial fibrillation.[66–69]

■ Nutritive Vessels and Nerves

The tissue of lung parenchyma is very well supplied with blood; the fact that it is venous is of no disadvantage, because O_2 is easily obtained from the air. Thus, nutrient supply from pulmonary arteries combined with O_2 supply from air appears to suffice not only for the parenchyma but also for bronchioles and the smaller pulmonary vessels, whose outer surface is almost directly exposed to air. The thicker-walled bronchi, with their glands and cartilage, require a nutrient blood supply from bronchial arteries.[15,70,71] These derive in part directly from anterior branches of the aorta and partly from the upper intercostal arteries. They course alongside the esophagus and penetrate on both sides into the hilum. The bronchial arteries extend to the most peripheral bronchi but not into the walls of bronchioles. On the other hand, some branches supply large pulmonary vessels as vasa vasorum, whereas others course along larger septa to reach the pleura. Some bronchial arteries form anastomoses with peripheral branches of the pulmonary arteries. There have been long discussions about the role that such anastomoses may play. It seems that in the normal lung their importance has been overrated. However, in certain pathologic conditions, such as bronchiectasis and tumors, the bronchial arteries and perhaps the bronchopulmonary anastomoses appear to play an important role. They also enlarge to form a collateral circulation when branches of the pulmonary artery are obliterated. The peribronchovascular space around larger pulmonary artery branches and bronchi with its capillaries from the bronchial circulation also has been proposed as a unique compartment since it is a preferential site of leukocyte infiltration and edema formation under pathologic conditions.[72] Furthermore, the bronchial circulation attenuates ischemia–reperfusion lung injury. Consequently, interruption of the bronchial circulation without revascularization during lung transplantation often leads to bronchial anastomotic complications.

Except for a few bronchial veins in the hilar region, the bronchial system does not have its own venous drainage into the systemic veins. Instead, the bronchial veins, which begin as a

AL GRAWANY

peribronchial venous plexus, drain into pulmonary veins; this drainage seems to constitute one source of normal venous admixture to arterial blood.

The lung is innervated by the autonomic nervous system. The parasympathetic fibers are derived from the vagal nerves and the sympathetic fibers from the upper thoracic and cervical ganglia; together they form the pulmonary nervous plexus in the region of the hilum before entering the lung. The fiber bundles follow the major bronchi and blood vessels, finally penetrating into the acini; some nerves also supply the pleura. In addition, motor nerves influence the smooth muscle tone of airways and blood vessels, and sensory nerves are involved in reflex functions (e.g., cough reflex, Hering–Breuer reflex). Moreover, the secretory function of glands as well as of secretory epithelial cells is at least partly under control of this nervous system. Nerve fibers are easily found in the wall of bronchioles and bronchi, where they often follow the course of bronchial arteries. However, fibers in alveolar septa are small and scarce.

THE CELLS OF THE ALVEOLAR REGION

The alveolar region of the lung is the region where gas exchange occurs. Its fundamental design and cellular components are discussed below.

Basic Design of the Gas-Exchange Barrier

Efficient gas exchange in the lung depends on a very thin barrier of very large surface between air and blood.[16,73] Actually, the barrier is so thin that it cannot be resolved into its constituents by light microscopy. Nevertheless, this barrier must be built of the three minimal tissue layers: an endothelium lining the capillaries, an epithelium lining the airspaces, and an interstitial layer to house the connective tissue fibers. The guiding principle in designing these cells must evidently be to minimize thickness and maximize extent. However, there is definitely a limit to this, set by the need to make the barrier and its constituent cells strong enough to resist the various forces that act on it: capillary blood pressure, tissue tension, and surface tension, in particular. Furthermore, the barrier must remain intact for a lifetime, and this requires continuous repair and turnover of the cells and their components. As a result, about half of the surface of the air–blood barrier is optimized for gas exchange in that the thin epithelial and endothelial cell extensions are only separated by a fused basement membrane. These areas are termed the thin parts of the air–blood barrier. Cell nuclei and connecting tissue fibers are concentrated in the so-called thick parts of the air–blood barrier.

In spite of this delicacy of tissue structure, we find that three-quarters of all the lung cells by volume or weight are contained in the lung parenchyma (Table 2-1). We also note that epithelium and endothelium make up about one-quarter each of the tissue barrier in the alveolar walls, whereas interstitial cells amount to 35%; the interstitial space with the connective tissue fibers makes up no more than 15% of the barrier.[11,74]

Alveolar Epithelium

The alveolar epithelium is a mosaic of different cell types. The vast majority of the total surface is lined by a single layer of squamous cells; the remaining fraction—only about 3% (Table 2-2)—is occupied by cuboidal secretory cells; one usually calls the squamous lining cells type I and the secretory cells type II alveolar epithelial cells or pneumocytes. Type I and II cells occur with a numeric frequency of about 1:2. A very rare third cell type, the brush cell, can be found in some specific regions near the entrance of the acinus (see above).

The fine structural details of the different types of alveolar epithelial cells can be fully visualized only by electron microscopy, whereas molecular markers selective for either type I or II cells or some of their constituents can be detected and localized by light microscopy (Fig. 2-15; Table 2-3).

TABLE 2-1 Estimated Cell Volumes in the Human Lung

The Pathway for Oxygen: Structure and Function in the Mammalian Respiratory System by Ewald R. Weibel, M.D., Cambridge, Mass.: Harvard University Press, Copyright © 1984 by the President and Fellows of Harvard College. Used by permission. All rights reserved.

Type I Alveolar Epithelial Cells

At first glance, the squamous type I cells show rather simple design features (Fig. 2-16). Their small, compact nucleus is surrounded by a slim rim of cytoplasm, where one finds a modest basic set of organelles, a few small mitochondria, and some cisternae of endoplasmic reticulum, seemingly the picture of a quiescent cell with no great metabolic activity.[11,75]

At the edge of the perinuclear region, a very attenuated cytoplasmic leaflet emerges (Fig. 2-16) and spreads out broadly over the basal lamina. This leaflet is made essentially of the two plasma membranes forming the apical and basal cell face, respectively, with a very small amount of cytoplasmic ground substance interposed (Fig. 2-17). Here one rarely finds any organelles except for the numerous plasmalemmal vesicles implied in the transcellular

TABLE 2-2 Morphometric Characteristics of Cell Population in Human Pulmonary Parenchyma

Cell Population	Percent of Total Cell Number[a]	Average Cell Volume (μm^3)	Average Apical Cell Surface (μm^2)
Alveolar epithelium

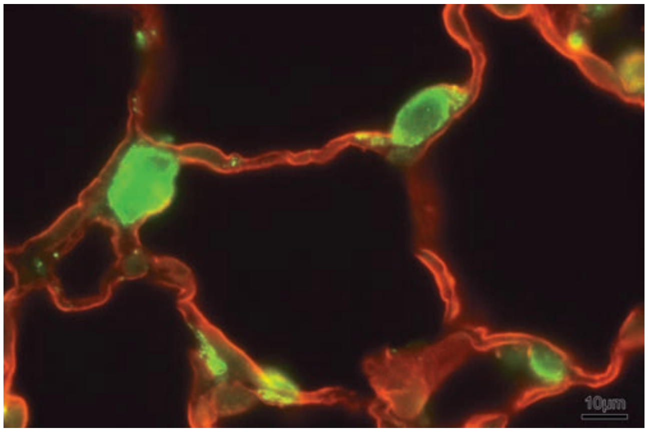

Figure 2-15 Immunofluorescent double labeling of alveolar epithelial cells. Type I cells are stained for Lycopersicon esculentum lectin *(red)*, type II cells are stained for SP-D *(green)*. Compare with Table 2-3. *(Micrograph reproduced with permission from H. Fehrenbach.)*

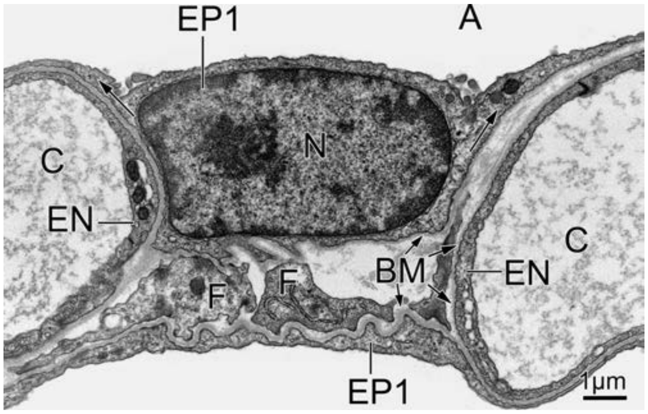

Figure 2-16 A type I alveolar epithelial cell (EP1) from human lung. The nucleus (N) is surrounded by very little cytoplasm, which extends as thin leaflets *(arrows)* to cover the capillaries (C). Note the basement membranes (BM) of the epithelium and endothelium (EN), which become fused in a minimal barrier. Interstitial space contains fibroblast processes (F).

transport of molecules. In fact, besides capillary endothelial cells, type I alveolar epithelial cells are among the richest in caveolae.

The surface covered by one type I epithelial cell is about 4000 to 5000 μm^2. In some texts one may find the type I cell called the "small alveolar cell" because of its small nucleus; clearly this is a misnomer, as the type I cell is a rather large cell indeed, with respect to both surface and cell volume (Table 2-2). Terminal bars are formed where the cytoplasmic leaflets of epithelial cells meet (Fig. 2-18). If one looks at the surface of the alveolar epithelium in scanning electron micrographs (Fig. 2-19), one notes that the patches covered by single type I cells are variable in size and that even the largest are much smaller than the 4000 to 5000 μm^2 given earlier, a number derived by dividing the total alveolar surface by the total number of type I cell nuclei. Why is this? There seem to be three to four times as many type I cell domains encircled by terminal bars as there are nuclei. Indeed, this observation was already made some 130 years ago by Albert Kölliker; his interpretation was that part of the alveolar surface was lined by "nonnuclear" cytoplasmic plates rather than by complete cells. It turns out that an alternative explanation is possible. One finds that type I cells are not simple squamous cells but rather branched cells with multiple apical faces, as shown diagrammatically in Fig. 2-20. Thus, what appears as nonnucleated plates are cytoplasmic domains connected to the perinuclear region by a stalk, spreading out on one side of the alveolar wall or the other; it is evident that several such domains may share a nucleus.[76–78]

Although type I cells cover about 97% of the alveolar surface area, they have long been neglected as being "silent," providing solely a barrier function. Although their overall function in the human lung

TABLE 2-3 Markers for Alveolar Epithelial Cells

Type I Cell	Type II Cell
HTI-56 (human)	Surfactant proteins:
T1α/RTI-40 (rat, mouse)	SP-A
Aquaporin 5	SP-B
Caveolin 1	SP-C
Receptors for advanced glycation end products (RAGE)	SP-D
	ABCA3
Carboxypeptidase M	HTII-280 (human)
Lectins:	RTII-70 (rat)
Lycopersicon esculentum	MMC4 (rat)
Bauhinia purpurea	Alkaline phosphatase
Ricinus communis 1	CD44
	Lectins:
	Maclura pomifera

These markers allow a selective distinction between type I and type II alveolar epithelial cells and can be visualized at a light microscopic level by immunohistochemistry, enzyme histochemistry, or lectin histochemistry. However, other cell types of the distal bronchiolar and alveolar region, e.g., club cells, capillary endothelial cells, or alveolar macrophages, also might stain positive for some of these markers. Data from Fehrenbach H. Alveolar epithelial type II cell: defender of the alveolus revisited. Respir Res. 2001;2:33–46; Griffiths MJD, Bonnet D, Janes SM. Stem cells of the alveolar epithelium. Lancet. 2005;366:249–260; Gonzales RF, Allen L, Gonzales L, Ballard PL, Dobbs LG. HTII-280, a biomarker specific to the apical plasma membrane of human lung alveolar type II cells. J Histochem Cytochem. 2010;58:891–901.

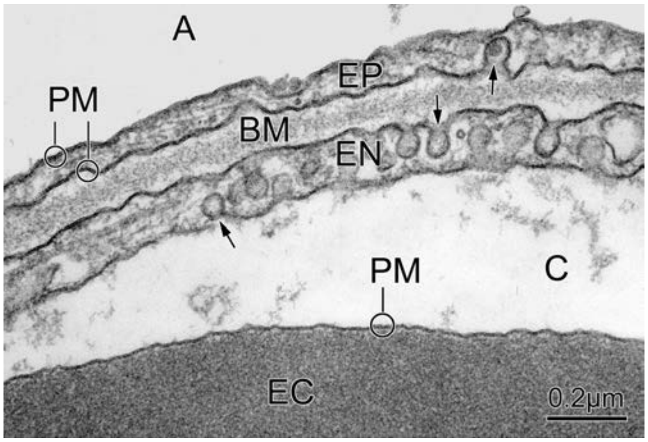

Figure 2-17 Thin, minimal tissue barrier between alveolar air (A) and capillary blood (C) is made of cytoplasmic leaflets of epithelium (EP) and endothelium (EN), joined by fused basement membranes (BM). Note that the epithelial and endothelial leaflets are bounded by plasma membranes (PM), as is the erythrocyte (EC). *Arrows* point to pinocytotic vesicles/caveolae. *(The Pathway for Oxygen: Structure and Function in the Mammalian Respiratory System by Ewald R. Weibel, M.D., Cambridge, Mass.: Harvard University Press, Copyright © 1984 by the President and Fellows of Harvard College. Used by permission. All rights reserved.)*

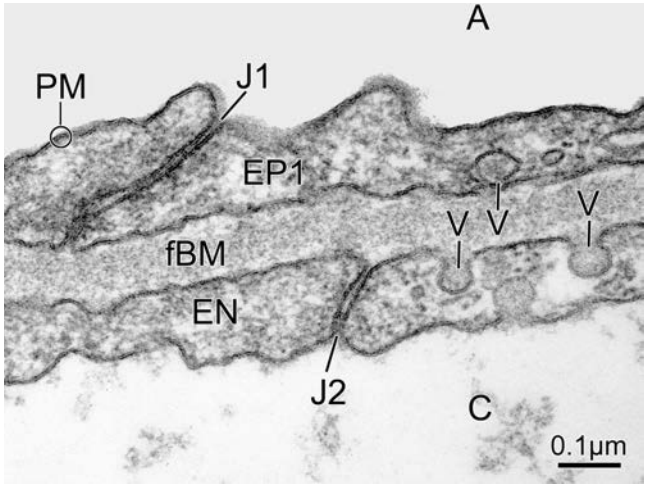

Figure 2-18 Minimal barrier part showing intercellular junctions. Between type I epithelial cells, a "tight" junction (J1) is formed by close apposition of the cell membranes over a comparatively wide band; the junction between endothelial cells (J2) is "leaky" because membranes become apposed over a narrow strip only. Note trilaminar structure of plasma membranes (PM), the occurrence of pinocytotic vesicles/caveolae (V) in both epithelium and endothelium (EN), and the fused basement membranes (fBM). A, alveolus; C, capillary; EP1, type I epithelial cell.

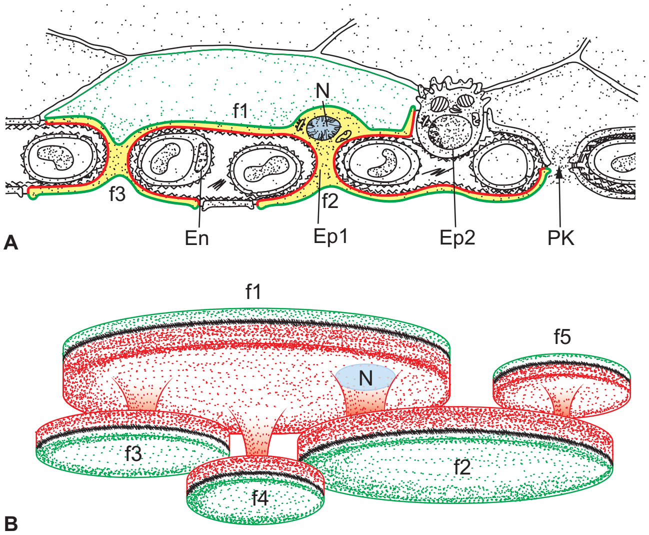

Figure 2-20 **A.** Diagram of section of alveolar septum with branched type I cell (yellow) forming the cytoplasmic plates: f1 (comprising the nucleus) and f2 plus f3 (connected with stalks to the nuclear area). The apical cell membrane is shown in green and the basal cell membrane in red, separated by the terminal bar (black dots). **B.** Topological diagram of this type I cell, in bottom-up view, showing the connection of the apical cytoplasmic facets (f2 to f5) by stalks to f1 and the nucleus (N). Note that the basal cell membrane (red) is a continuum, whereas the apical membrane (green) is fragmented into facets. The black bands represent the terminal bars on the lateral surfaces. En, endothelial cell; Ep1, type I epithelial cell; Ep2, type II epithelial cell; PK, pore of Kohn.

remains to be determined, animal and in vitro studies strongly suggest that type I cells are actively involved in alveolar ion and fluid homeostasis.[79–81]

Type I cells are easily damaged, particularly because of their extensive surface area and their complex branching architecture. However, there is an additional problem: one finds that type I cells are not capable of multiplying by mitosis in vivo, neither during lung growth when more cells are needed to coat the expanding alveolar surface nor upon damage in the adult lung when cells need to be replaced. In both instances new type I cells are made by mitotic division and transformation of type II cells, a process that takes about 2 to 5 days.

This seems to work under normal circumstances. There are, however, conditions where this repair mechanism is too slow to cope with excessive damage, so that a syndrome of severe respiratory failure, acute respiratory distress syndrome (ARDS), develops, which requires intensive care treatment. In such patients one finds large parts of the type I cell lining of the alveolar surface to be destroyed. As a consequence, the barrier has become leaky and the alveoli fill with alveolar edema, so that they can no longer take part in gas exchange.[82,83]

With proper medical care, this alveolar edema can often be resolved within a few days. The alveoli become again filled with air, but in spite of this, gas exchange does not improve. What has

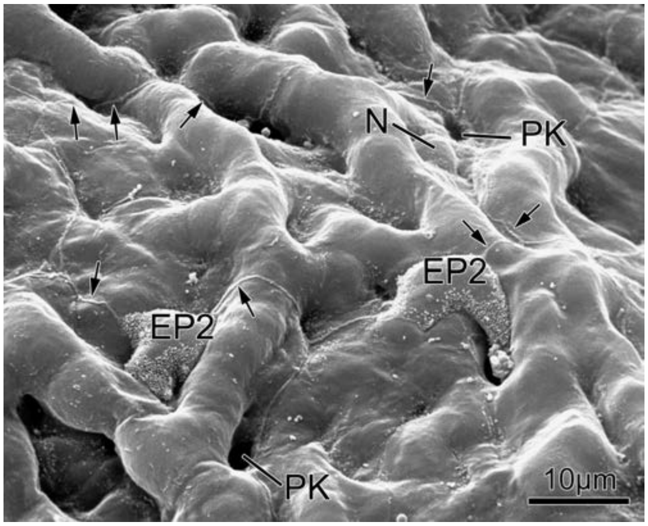

Figure 2-19 Surface of the alveolar wall in the human lung seen by scanning electron microscopy reveals a mosaic of alveolar epithelium made of type I and type II (EP2) cells. *Arrows* indicate boundary of the cytoplasmic leaflet of the type I cell which extends over many capillaries. Note the two interalveolar pores of Kohn (PK). N, nucleus of type I cell.

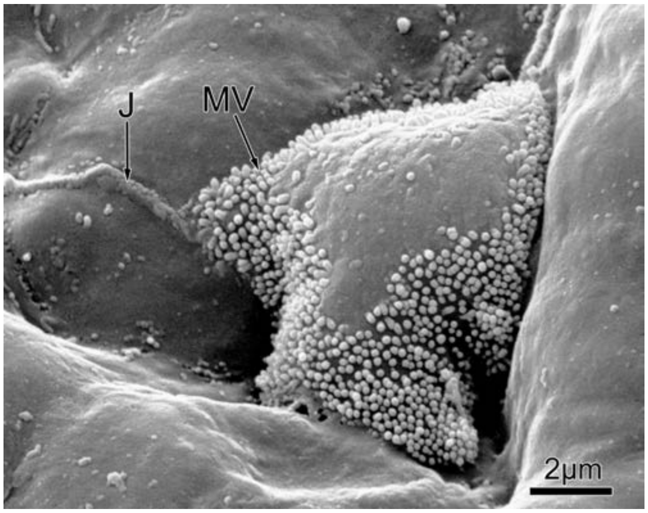

Figure 2-21 Higher magnification of a type II cell reveals a "crown" of short microvilli (MV) and a central "bald patch." Note junction lines of type I cells (J) meeting with the type II cell.

happened is that the repair of the severely damaged alveolar epithelium requires a lot of new cells to be made by division of type II cells.[84] These form a rather thick cuboidal lining of the barrier surface, a phenomenon termed *cuboidal metaplasia*, and this thick barrier offers a high resistance to O_2 flow. It takes several weeks until a thin barrier is restored by transformation of the cuboidal cell lining into delicate type I cells. During this process, the cells go through intermediate stages where they are often positive for both type II and type I cell markers.[85,86]

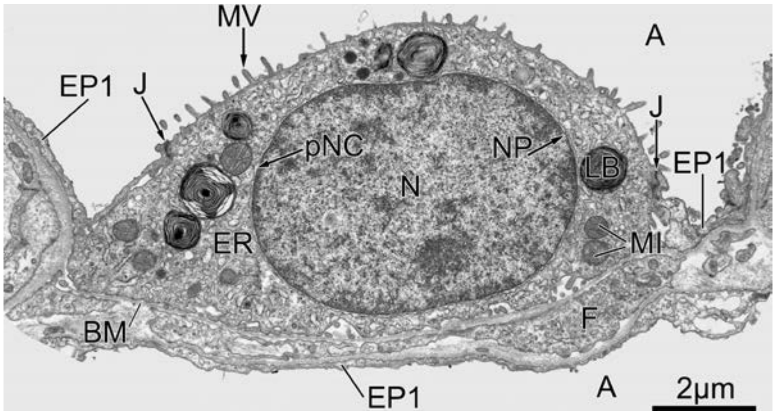

Figure 2-22 A type II epithelial cell from the human lung forms junction (J) with type I epithelial cells (EP1). Its cytoplasm contains osmiophilic lamellar bodies (LB) and a rich complement of organelles: mitochondria (MI), endoplasmic reticulum (ER), and so on. The nucleus (N) is surrounded by a perinuclear cisterna (pNC) which is perforated by nuclear pores (NP). A, alveolus; BM, basement membrane; F, fibroblast; MV, microvilli.

Type II Alveolar Epithelial Cells

The type II alveolar epithelial cell is a conspicuous but in fact relatively small cell whose mean volume is less than half that of the type I cell (Table 2-2), although it is often called the "large alveolar cell."[11] Its shape is cuboidal, the apical cell surface bulges toward the lumen and is provided, mostly around its periphery, with a tuft of microvilli (Figs. 2-21 and 2-22). Often, type II cells seem to be preferentially located in the corners of alveoli or in close proximity to interalveolar pores of Kohn. They are usually found as solitary cells; only in cases of alveolar epithelial damage, proliferation of type II cells leads to focal clusters during the repair process. Occasionally, a single type II cell might supply two or even three adjacent alveoli with its apical surface. The basement membrane beneath type II cells is occasionally interrupted. Through these apertures, foot processes of type II cells can extend to the interstitium and come in close proximity to interstitial cells.[87]

Type II cells contain a wealth of cytoplasmic organelles of all kinds (Fig. 2-22): mitochondria, a lot of endoplasmic reticulum with ribosomes, and a well-developed Golgi complex surrounded by a set of small lysosomal granules among which so-called *multivesicular bodies*—membrane-bounded organelles containing a group of small vesicles—stand out (Fig. 2-23). In addition, one finds the characteristic lamellar bodies, larger membrane-bounded secretory organelles that contain densely packed phospholipid lamellae. There are notable species differences in the ultrastructural organization of lamellar bodies. In rodents, the lamellae are mostly arranged in parallel stacks whereas in humans, concentrically arranged lamellae are mostly found, which are attached to a projection core consisting of randomly arranged short stacks of densely packed membrane segments (Fig. 2-24).[88] The periodicity of the lamellae is in the range of 4 to 6 nm. One human type II cell contains between 200 and 500 lamellar bodies, making up a total volume of about 2 cm^3 in the entire lung. With a diameter of approximately 1 μm, lamellar bodies are among the largest secretory organelles of all cells in the body. Owing to their equipment with lysosomal enzymes (e.g., acid phosphatase, cathepsins) and proteins (e.g., members of the lysosomal membrane protein [LAMP] family) and their acidic pH of about 5.5, lamellar bodies are regarded as secretory lysosome-related organelles.[89]

Type II cells have two main functions: they serve as the cellular source of pulmonary surfactant and they contribute to the regeneration of the alveolar epithelium under physiologic and pathologic conditions. These properties form the basis of the concept of the type II cell as the "defender of the alveolus."[90–92]

Surfactant prevents alveolar atelectasis by a surface area–dependent reduction of the alveolar surface tension (see below).[93–96] Another function of surfactant as a result of the reduction of alveolar surface tension is to prevent the formation of intra-alveolar edema.[97] In addition, certain surfactant components have important immunomodulatory functions in the innate host defense system.[98,99] Taken together, the main functions of surfactant might be summarized as to keep alveoli open, dry, and clean. Surfactant is composed of around 90% lipids, mainly saturated phosphatidylcholine, and around 10% proteins, including the surfactant apoproteins termed SP-A, SP-B, SP-C, and SP-D. Besides its biochemical complexity, surfactant is also morphologically very heterogeneous, consisting of different surfactant subtypes with highly organized structure that represent different stages in metabolism (Figs. 2-24–2-26).[88,100]

The alveolar epithelium (including interalveolar pores of Kohn) is lined by a thin but apparently continuous fluid layer inserted between the apical cell membrane and the surface film, thus forming a duplex lining layer.[101,102] Surfactant functions in and on this layer. It is synthesized, stored, secreted, and to a large extent recycled by type II cells.[88,91,103] Therefore, an intracellular surfactant pool present

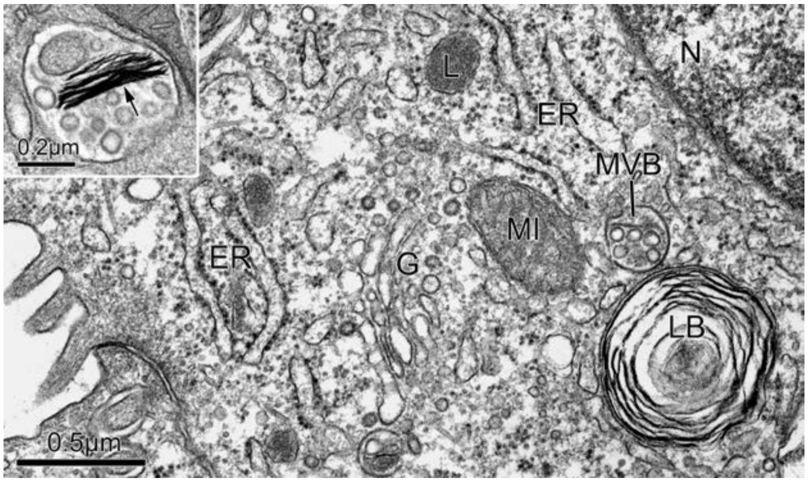

Figure 2-23 Cytoplasmic organelles of the type II cell implicated in the synthesis of surfactant are the endoplasmic reticulum (ER), Golgi complex (G), lysosomes (L), multivesicular bodies (MVB), and finally lamellar bodies (LB). The *inset* shows a large composite body with a stack of phospholipid lamellae *(arrow)*. N, nucleus. *(The Pathway for Oxygen: Structure and Function in the Mammalian Respiratory System by Ewald R. in type II cells and an intra-alveolar surfactant pool present at the surface of the fluid alveolar lining layer as well as within its hypophase can be distinguished. The intracellular storage form of surfactant is represented by lamellar bodies. Prior to storage, the synthesis of surfactant material involves endoplasmic reticulum, (at least partly) Golgi complex, and multivesicular bodies. In type II cells, multivesicular bodies participate in the posttranslational processing of surfactant proteins as well as in endocytosis and subsequent recycling and/or degradation of surfactant material; thus, most probably representing the junction point between the biosynthetic and endocytotic pathway. In addition, transitional forms between multivesicular bodies and lamellar bodies, termed *composite bodies*, have been described. Surfactant material present in lamellar bodies is secreted into the alveolar lumen via exocytosis (Figs. 2-25 and 2-26).

Most surfactant components are assembled in lamellar bodies prior to secretion (Figs. 2-24–2-26)—at least the lipid fraction and the hydrophobic surfactant proteins, SP-B and SP-C, whereas the hydrophilic surfactant proteins SP-A and SP-D seem to be secreted independently via a constitutive pathway bypassing the regulated exocytosis of lamellar bodies. Lamellar body secretion starts with the fusion of its limiting membrane with the apical plasma membrane, followed by formation of a fusion pore, and finally the slow release of surfactant material through the pore. The diameter of the pore is considerably smaller than that of the lamellar body. Thus, surfactant seems to be squeezed through the pore.[104] The mechanisms that regulate surfactant secretion in vivo are still not fully elucidated. It seems that, among the various stimuli that can act via several different signaling pathways, mechanical stretch during ventilation—either as a direct effect on

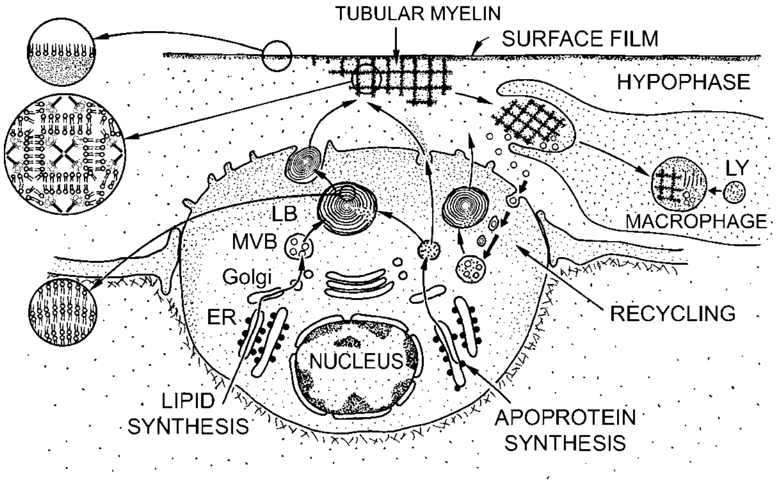

Figure 2-25 Schematic diagram of pathways for synthesis and secretion of surfactant lipids and apoproteins by a type II cell, for their recycling by type II cells, and for their removal by macrophages. Note the arrangement of phospholipids and apoproteins in the lamellar bodies, in tubular myelin, and in the surface film. *(The Pathway for Oxygen: Structure and Function in the Mammalian Respiratory System by Ewald R. type II cells or indirectly via type I cells or capillary endothelial cells which may act as "strain sensors"—is the physiologically most relevant.[91,103,105,106]

Intra-alveolar surfactant consists of several subtypes, namely freshly secreted lamellar body-like forms, tubular myelin, the surface film, and small unilamellar vesicles. After secretion, lamellar body-like forms in the hypophase associate with SP-A, which is separately secreted by type II cells,[107] and undergo a major structural transformation into tubular myelin figures with a unique lattice-like structure.[108] The precise physiologic function of tubular myelin, however, is still unclear. Tubular myelin is thought to be the immediate precursor of the surface film, although the existence of an additional multilayered surface-associated surfactant reservoir underneath the surface film has been suggested.[100,109] "Spent" surfactant components are found in the hypophase as small unilamellar vesicles. The major route of surfactant clearance is reuptake by type II cells. Within type II cells, surfactant material can either be recycled or degraded. Other routes of surfactant clearance include ingestion and lysosomal degradation by alveolar macrophages and clearance via the airways.

After differential centrifugation of intra-alveolar surfactant material harvested by bronchoalveolar lavage, surface active large aggregates (LA), ultrastructurally largely corresponding to lamellar body-like forms and tubular myelin, and inactive small aggregates (SA), ultrastructurally largely corresponding to unilamellar vesicles, can be distinguished. Thus, the SA/LA ratio can be used to assess the biophysical activity of surfactant.[94,95]

A surfactant film, most likely mainly transported upward from the alveoli, is also present in the airways. Here, surfactant prevents collapse of smaller airways, prevents transepithelial fluid influx, enhances mucociliary transport, and interacts with inhaled pathogens and particles. At least some of the surfactant proteins are also synthesized and secreted by club cells. Club cells express SP-B, but not SP-C, which is exclusively expressed by type II cells. There is some controversy regarding whether club cells express SP-A and SP-D. Although this is obviously the case in rodents, club cells in the normal adult human lung most likely express very low or no SP-A and SP-D.[107,110,111] It seems that club cells are not involved in reuptake or recycling of surfactant components.[112] However, their overall role in surfactant biology is not yet defined.

The surfactant apoproteins as the "smart molecules in the surfactant system"[113] have important functions in surfactant subtype assembly, surfactant biophysics, surfactant homeostasis, and innate immunity.[114–118] The hydrophilic proteins SP-A and SP-D belong to the collectin protein family involved in innate immunity. In addition, SP-A, together with SP-B, is important for tubular myelin formation, thus stabilizing active surfactant forms, whereas the hydrophobic proteins SP-B and SP-C and, in conjunction, SP-A enhance the adsorption of phospholipids into the surface film. SP-A might also inhibit surfactant secretion and stimulate surfactant reuptake by type II cells.

Differences in the ultrastructural organization of intracellular and intra-alveolar surfactant subtypes between humans and rodents are also reflected by a different distribution of surfactant proteins (Fig. 2-24).[88] In the human lung, SP-A within type II cells is mainly found in small vesicles and multivesicular bodies and only rarely at the periphery of lamellar bodies. In the alveolar lumen, SP-A is associated with peripheral membranes of lamellar body-like forms in close proximity to tubular myelin, in the corners of the tubular myelin lattice structure, and partly at the surface film and unilamellar vesicles.[107] SP-B in the human lung is localized in the projection core of lamellar bodies within type II cells and in dense core particles associated with tubular myelin in the alveolar lumen.[119]

The crucial role of the surfactant system for the maintenance of the functional integrity of the lung is clearly demonstrated by surfactant dysfunction disorders, which can be caused either at birth by developmental deficiency (owing to lung immaturity or mutations affecting surfactant synthesis or secretion) or later by acquired dysfunction (owing to damage of type II cells or inhibition/inactivation of intra-alveolar surfactant).[94,95,120] A primary deficiency of surfactant in the immature lungs causes the respiratory distress syndrome of premature neonates (RDS). Surfactant dysfunction mutations causing either acute respiratory failure or chronic lung disease after birth have been identified in the genes encoding for SP-B, SP-C, and the ATP-binding cassette transporter ABCA3, which is present at the limiting membrane of lamellar bodies. Impairment of an originally intact surfactant system is involved in the pathogenesis of a variety of other lung diseases, such as acute lung injury/ARDS as well as obstructive, infectious, and interstitial lung diseases. Mechanisms leading to impaired surfactant activity include apoptotic or necrotic cell death of type II cells, damage of surfactant proteins and lipids by reactive oxygen and nitrogen species, and enzymatic damage by phospholipases or neutrophil elastase. In addition, plasma proteins entering the alveolar space during edema formation also are known to inactivate surfactant.

With a turnover time of about 4 to 10 hours and only a rather small intracellular surfactant reserve available for secretion onto the large alveolar surface, the ability to cope with a lack of active surfactant during lung injury is limited. Hence, there is a rationale to supplement the surfactant material available in cases of surfactant deficiency or damage. One of the major advances in neonatology in our time has been the development of surfactant replacement therapy for the treatment of RDS. The story of the treatment of premature babies with exogenous surfactant is indeed a paradigmatic example in which discoveries from basic research were successfully applied to an important clinical problem.[95,121–123] The indications for surfactant replacement therapy have widened in recent years, with promising results in forms of respiratory failure not caused by a primary deficiency of endogenous surfactant but rather by impairment of an originally intact surfactant system. In these cases, however, the efficacy of exogenous surfactant therapy very much depends on the ability of the surfactant preparation to resist the inhibition/inactivation that caused alterations of the endogenous system.

■ Capillary Endothelium

The alveolar septa of the adult lung contain a single capillary network. The capillary endothelium is of the continuous (non-fenestrated) type. Alveolar capillaries are provided with pericytes, but they are rarer and less densely branched than pericytes of the systemic circulation.[124] Pericytes are related to vascular smooth muscle cells in that they both are contractile perivascular cells. Thus, pericytes protect microvessel wall integrity by providing some mechanical support. However, in contrast to vascular smooth muscle cells, pericytes are embedded within the endothelial basement membrane, frequently forming contacts with capillary endothelial cells. They seem to contribute components to the capillary basement membrane and extracellular matrix and secrete vasoactive substances. In addition, pericytes are thought to be involved in the regulation of endothelial cell proliferation and differentiation and to act as progenitor cells for other cell types.[125–129]

Capillary Endothelial Cells

At first glance, capillary endothelial cells resemble type I alveolar epithelial cells, but in contrast to type I cells with their complex branching architecture, capillary endothelial cells form simple sheets (Fig. 2-27).[59] Moreover, compared with the tight occluding junctions between alveolar epithelial cells that constitute a powerful seal of the intercellular cleft, the occluding junctions between capillary endothelial cells are rather leaky, allowing a nearly uninhibited exchange of water, solutes, and even some smaller macromolecules between the blood plasma and the interstitial space (Fig. 2-18). Occluding junctions between capillary endothelial cells are often located at the transition of the thin to the thick part of the air–blood barrier and are often covered by pericytes.

There is another notable and important difference between the two basically similar lining cells on the epithelial and endothelial side of the gas-exchange barrier: their size. Although the capillary surface is some 10% to 20% smaller than the alveolar surface, the capillary endothelial cells are about four times more numerous than type I cells[74]; this means that the surface covered by one type I epithelial cell must be about four times larger, namely 4000 to 5000 μm^2, compared with about 1000 μm^2 in endothelial cells (Table 2-2).

Numerous caveolae are found in capillary endothelial cells (Figs. 2-17 and 2-18). However, at the bulging part of the capillaries, some parts of the endothelial cell extensions are free of caveolae and are thinned down to a thickness of about 20 to 30 nm, basically consisting of the two plasma membranes with only a minute amount of cytoplasm in between. These areas, rarer in human lungs than in rodents, are termed the *avesicular zone* of the alveolar capillary endothelium.[11,59] In contrast to the endothelium of conducting vessels, Weibel–Palade bodies are missing in capillary endothelial cells, thereby underscoring the structural and functional differences between alveolar and extra-alveolar endothelial cells.[11,51,129,130] There is even specialization among alveolar capillary endothelial cells: Those at the thick parts of the air-blood barrier are similar to endothelial cells in capillaries of other organs. They function as progenitor cells, whereas those at the thin parts cover a larger surface area and are more widely ramified.[131]

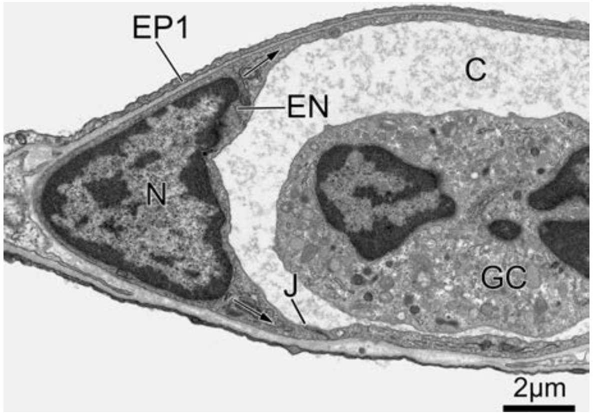

Figure 2-27 An endothelial cell (EN) of capillary (C) is similar in basic structure to a type I epithelial cell (EP1). The nucleus is enwrapped by little cytoplasm but thin leaflets extend as capillary lining *(arrows)*. Note the intercellular junction (J) and a white blood cell/granulocyte (GC), in the capillary. *(The Pathway for Oxygen: Structure and Function in the Mammalian Respiratory System by Ewald R. Weibel, M.D., Cambridge, Mass.: Harvard University Press, Copyright © 1984 by the President and Fellows of Harvard College. Used by permission. All rights reserved.)*

■ Interstitium

The interstitium of the alveolar septum is for the most part extremely thin. At the thick parts of the air–blood barrier where epithelial and endothelial basement membranes are separated, one finds elastic fibers and bundles of collagen fibrils in the extracellular matrix as well as interstitial cells, mainly fibroblasts, the cells responsible for production of extracellular matrix components (Figs. 2-28 and 2-29). The

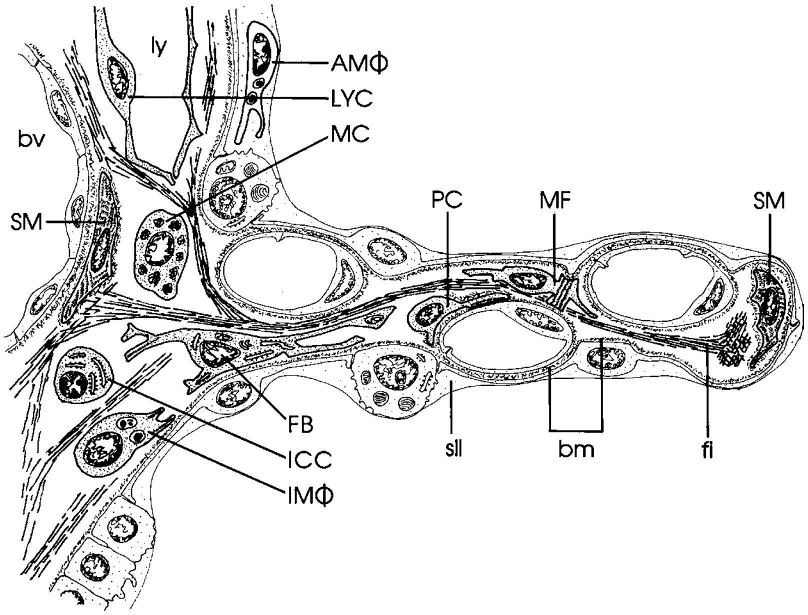

Figure 2-28 Schematic diagram of the structural organization of the alveolar interstitium. The alveolar septum extends between a free edge *(right)* and a perivascular connective tissue sleeve *(left)*, enwrapping a blood vessel (bv). Basement membranes (bm) are associated with epithelium and endothelium, and they bound the interstitial space. Fiber strands (fi) form a continuum. Interstitial cells include: fibroblasts (FB), myofibroblasts (MF), smooth muscle cells (SM), pericytes (PC), various kinds of immune competent cells (ICC), mast cells (MC), lymphatic endothelial cells (LYC), and histiocytes or interstitial macrophages (IMΦ). Alveolar macrophages (AMΦ) are submerged in the alveolar surface lining layer (sll)., ly, lymphatic capillary. *(Reproduced with permission from Crystal RG, West JB, Weibel ER, et al: The Lung: Scientific Foundations, 2nd ed. New York, NY: Lippincott-Raven; 1997.)*

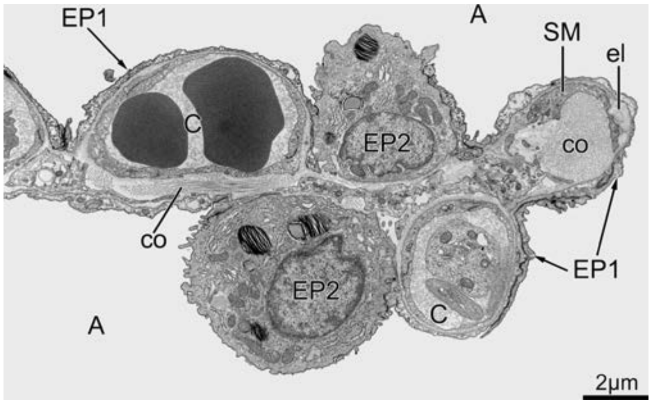

Figure 2-29 Alveolar septum with free edge *(right)* showing reinforced entrance ring with elastic fibers (el), collagen fibrils (co), and smooth muscle cell (SM). The two capillaries (C) are on different sides of the septum, as are the two type II cells (EP2). precise arrangement of the connective tissue fibers will be discussed later in relation to the mechanical properties of the lung.

Interstitial Cells

The resident interstitial cells of the alveolar septum comprise fibroblasts and contractile cells (myofibroblasts, lipofibroblasts, smooth muscle cells, and pericytes) (Fig. 2-28). Free interstitial cells are part of the defense system usually found in the juxta-alveolar connective tissue sleeves (see below) and include interstitial macrophages (histiocytes), mast cells, and under certain conditions, lymphocytes, plasma cells, and granulocytes.

Fibroblasts are a heterogeneous cell population. Many fibroblasts have notable contractile properties; therefore, they have been termed *myofibroblasts*. Myofibroblasts contain bundles of microfilaments anchored in patches beneath the plasma membrane. These filament bundles span the entire width of the cell. At the places where the microfilament bundles are connected to the plasma membrane, attachments to the epithelial and/or endothelial basement membrane exist.[11,132,133] Through holes in the basement membranes, myofibroblasts directly link alveolar epithelial and capillary endothelial cells.[87]

Some contractile fibroblasts are equipped with nonmembrane–bound lipid bodies, thus termed *lipid interstitial cells* or *lipofibroblasts*.[134,135] These cells are more common in rodent than in human lungs and occur particularly during alveolar development and growth. Lipid bodies consist of an osmiophilic rim of amphipathic phospholipids, glycolipids, sterols and specific proteins, and a hydrophobic core of neutral lipids. In many cell types, lipid bodies represent specialized domains for the synthesis of eicosanoid mediators.[136] Pulmonary lipofibroblasts seem to be related to the lipid-containing perisinusoidal cell (Ito cell) in the liver in that they might serve as a storage depot for retinoids.[135,137] Under certain conditions, lipofibroblasts might provide fatty acid substrates for surfactant synthesis in type II cells.[135]

The occurrence of smooth muscle cells in the alveolar septa is mostly restricted to the free septal edges where they contribute to the network of alveolar entrance rings (Figs. 2-28 and 2-29). Pericytes abut alveolar capillaries (see above).

STRUCTURAL ASPECTS OF THE DEFENSE SYSTEM OF THE LUNG

The large and delicate alveolar surface is constantly challenged by inhaled microorganisms and particulate matter. Thus, normal lung function critically depends on an efficient defense system.[98,117,138–141]

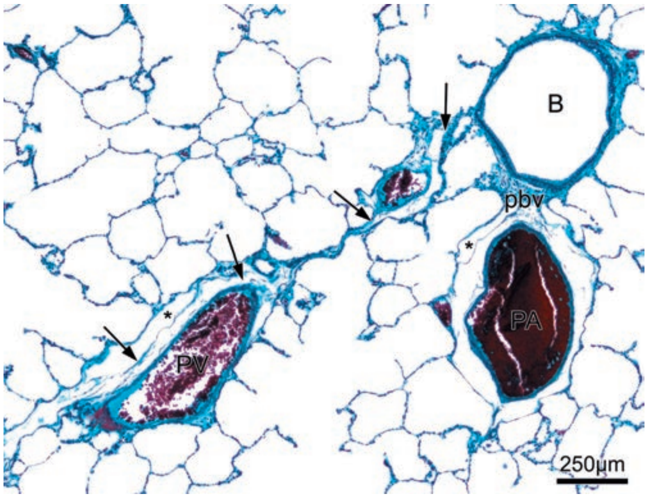

Figure 2-30 Light micrograph of human lung showing connective tissue sleeve *(arrows)* extending from the peribronchovascular space (pbv) around branch of pulmonary artery (PA) and bronchiolus (B) to pulmonary vein branch (PV). Asterisks, lymphatic.

At the alveolar level, the primary defense barrier is the alveolar lining layer. Here, alveolar macrophages are the sentinel phagocytic cells of the innate immune system, as we shall discuss later. In addition, protein components of the innate immune system, including the lung collectins SP-A and SP-D as well as a variety of other antimicrobial peptides (e.g., lysozyme, lactoferrin, defensins, cathelicidins), are present in the alveolar lining layer.

Another set of macrophages forms a second defense line just beneath the alveolar epithelium; that is, in the interstitial space of the lung parenchyma. In the normal lung, these interstitial macrophages (histiocytes) are not found in alveolar septa; instead, they occur only in the connective tissue sleeves at the periphery and in the center of acini where the peripheral fiber system connects with the adventitial sheath of bronchioles and pulmonary arteries (Fig. 2-30). Thus, they are found in regions where lymphatics begin their course toward the major airways in the hilar region where lymph nodes are found. In these juxta-alveolar regions of connective tissue, we usually find the common elements of the defense system (Figs. 2-30 and 2-31). These include lymphatic vessels and several mobile cells. Interstitial macrophages are constantly being

replenished by blood monocytes migrating into the interstitial space. Sometimes they become permanent residents in the form of storage cells for "indigestible" foreign matter, such as carbon particles and silicates. The relationship between interstitial macrophages and dendritic cells (see below) is under discussion.[142,143] Lymphocytes are less common and are mostly present as T cells whereas B cells and natural killer cells are rare in the normal lung. Granulocytes (neutrophils, eosinophils, and basophils) are present in the human lung, but they also are very rare. Mast cells contain granules storing heparin and histamine as well as peptidases such as tryptases and chymases[144] that, in the human, show a characteristic scroll-like substructure (Fig. 2-32) as well as lipid bodies. According to their anatomic location, they show site-specific characteristics, thus displaying considerable heterogeneity.[145] Antigen-presenting dendritic cells possess long branched dendritic cell processes (hence, their name) and an irregular, folded nucleus. Phagolysosomes are absent. Once activated, dendritic cells migrate to lymph nodes where they induce the proliferation of antigen-specific T cells, thus providing a link between innate and adaptive immunity. In addition to their presence within the lung parenchyma, dendritic cells are found within the tracheal and bronchial epithelium where they seem to form a network comparable to the Langerhans cells in the epidermis. Like Langerhans cells, airway dendritic cells are characterized by pentalaminar platelike organelles (Birbeck granules).[146–148] In the ciliated epithelium of bronchi and bronchioles diapedesis is seen—that is, lymphocytes and other leukocytes in the process of penetrating the epithelium to reach the mucus blanket. Plasma cells occur in relatively high numbers around the acini of the seromucous glands of bronchi (Fig. 2-7); hence, it is likely that antibodies are being secreted into the mucus blanket by these glands by a process similar to that occurring in the salivary glands or in the glands of the nasal mucosa.

The third defense line is constituted by the lymph nodes, which are arranged along the major bronchi and extend to subsegmental bronchi about 5 mm in diameter (Fig. 2-33). The most peripheral lymph nodes are tiny, a mere 1 to 2 mm in diameter, but closer to the hilum they become larger, reaching 5 to 10 mm in diameter in the region of the tracheal bifurcation and along the trachea. The lymph nodes from adult human lungs often appear gray or even black because of deposition in the medullary cords of large numbers of macrophages loaded with carbon pigment. This material entered the lung via the airways, primarily as smoke, soot, or coal dust; depending on the size of the particles, they either were deposited on the surface of conducting airways or reached the alveoli. The further down the deposition, the greater the likelihood that this material cannot be eliminated while in the airways, that is, within the mucus blanket. The only exit from the lung parenchyma then is via the lymphatics, but this exit ultimately leads to the blood, a circumstance that is obviously to be avoided. Filtering the lymph in lymph nodes and providing a depository in the medullary cords protects the blood and hence the entire organism from dissemination of indigestible foreign matter and also, in most instances, of infective agents.

Thus, the lymphatic "circulation" in the lung plays an important defense role.[6,44] It is unidirectional. It begins as interstitial fluid that seeps from the capillaries and is efficiently drained along the connective tissue fibers toward those connective tissue sleeves in the center and at the periphery of acini where lymph capillaries begin. From there, lymphatic vessels, endowed with valves and an irregular smooth muscle wall, course in septal structures, in the pleura, and peribronchial and perivascular sheaths toward the hilar region (Fig. 2-33). Lymph nodes are intercalated in the course of the lymphatics, which lead the lymph toward the tracheal bifurcation and then along the trachea into the right and left mediastinal lymph

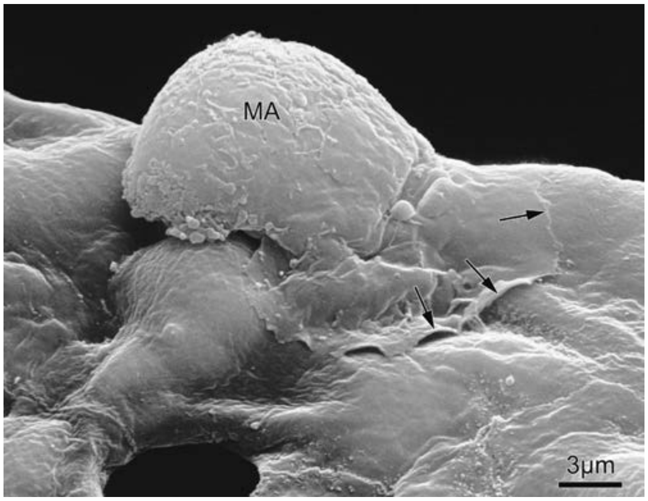

Figure 2-34 Alveolar macrophage (MA) seen sitting on epithelial surface of human lung. Note cytoplasmic lamella *(arrows)* which represents the advancing edge of the cell.

channels. The right channel drains into the right subclavian vein; the left, together with the thoracic duct, into the left subclavian vein. Because of the many anastomoses connecting parallel lymphatics, a particular lymph node receives lymph from various lung regions, but the closest regions tend to predominate.

■ Alveolar Macrophages

Lung macrophages can be differentiated into several populations according to the compartment in which they are found: intravascular, interstitial, airway, and alveolar macrophages.[149–152] Of these, the alveolar macrophages, the cell population of the surface lining layer, are of particular importance. They are free cells, endowed with a high phagocytic capacity, which are transiently attached to the surface of the alveolar epithelium by pseudopodia and can crawl over this surface by amoeboid movement (Fig. 2-34). Occasionally, alveolar macrophages can be observed during the passage through an interalveolar pore of Kohn. However, they are submerged beneath the surface film of phospholipids (Fig. 2-35) and, therefore, are part of the surface lining layer of alveoli, more specifically of its hypophase. Alveolar macrophages exert their phagocytic activity within the surface lining layer (Fig. 2-25). Hence, it is not surprising that their vacuoles contain large amounts of ingested surfactant material, in part even tubular myelin. The importance of alveolar macrophages for surfactant removal is underscored by the acquired form of pulmonary alveolar proteinosis, where a defect in surfactant catabolism by alveolar macrophages caused by autoantibodies against granulocyte/macrophage colony-stimulating factor (GM-CSF) leads to an accumulation of surfactant material in the alveoli.[153]

Alveolar macrophages are initially derived from monocytes—indirectly, therefore, from hematopoietic cells—and probably reach the alveoli in two steps: first, by settling in the pulmonary interstitial tissue, and second, by migration from the interstitial tissue into the alveoli where they constitute a partly self-reproducing cell population. Under certain circumstances, e.g., during inflammation, this resident pool can be supplemented by alveolar macrophages freshly recruited from circulating monocytes.[154,155] Their removal seems to involve two different pathways: (1) some of the macrophages undoubtedly move up the bronchial tree in the mucus blanket and eventually appear in the sputum; and (2) others possibly return into the interstitial space. In the normal lung, however, the second path seems to occur exclusively in those alveoli that abut the connective tissue sleeves around larger vessels and conducting airways or on interacinar septa; that is, where the lymphatic capillaries are located. A preferred location appears to be in the respiratory bronchioles at the entrance into the acinus or in the center of the acinus, where one often finds congregations of dust-laden macrophages; this may be at the origin of centroacinar damage observed in smokers, which leads to progressive emphysema. In these places, macrophages either settle as carbon pigment-loaded histiocytes, or they leave the lung parenchyma via lymphatics (Fig. 2-31) to settle in the lymph nodes. The way in which macrophages and/or their ingested material are transferred from the alveolar surface to the interstitial space is still unknown.

FUNCTIONAL DESIGN OF THE LUNG

From the preceding section it has become apparent that the lung is built of a multitude of cells and tissue elements that all serve specific functions in support of the lung's main function: the exchange of oxygen and carbon dioxide between the air and the blood. But it takes more than cells to make a good lung.[156] The lung's multiple component structures must be integrated to make an efficient and stable gas exchanger, and this demands a blueprint for the integral architecture of the human lung.[7] This must first ensure that the airways and blood vessels are adequately correlated topologically and quantitatively to allow well-matched ventilation and blood flow. It must also realize a complex organization that allows air ventilation, blood perfusion, and gas exchange to function in the most efficient manner. The design principles that govern the architecture of the human lung toward that goal can be characterized as *Complexity, Correlativity,* and *Connectivity*. Complexity means that the microscopic gas-exchange units are an integral part of the macroscopic airways and vessels; their architectural correlation determines the efficient approximation of air and blood in the gas exchanger; and connecting all the parts into a whole is achieved with a fiber continuum that pervades the entire lung. The implementation of these principles during development is decisive for "making a good lung."

■ Design of the Branching Airway Tree

The entrance to the lung's airways is the trachea (Fig. 2-3), a single tube. The gas-exchange elements where air and blood are brought into close contact are contained in several million units. Between entrance and periphery lies a meticulously designed system of branching airways that serve to conduct the inspired air into those peripheral channels that carry alveoli in their walls and can thus contribute to the exchange of gases between air and blood (Fig. 2-5).[8]

In the mammalian and human lung the airways are built as dichotomous trees.[157] This is the result of lung morphogenesis where the end bud of each airway tube gives rise to two daughter branches. In the human lung this goes on for 23 generations, on average, and, since the number of branches doubles with each generation, there are 2^{23} or about 8 million end branches, generally called *alveolar sacs*.[8] This is an average value; in reality the number of branching generations needed to reach the alveolar sacs is quite

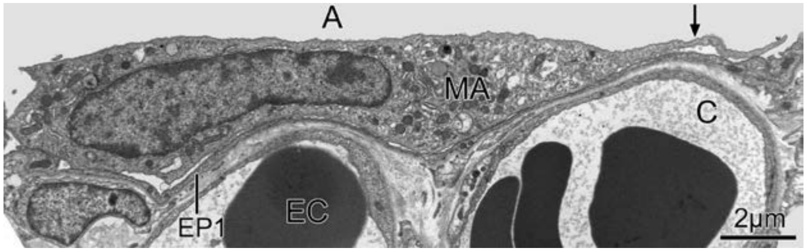

Figure 2-35 Alveolar macrophage (MA) fixed in its natural position of "flat" attachment to the alveolar epithelium. *Arrow* points to advancing cytoplasmic leaflet.

AL GRAWANY

variable, ranging from about 18 to 30. This variability results from the fact that the airways form a space-filling tree (Fig. 2-3) whose endings must be homogeneously distributed in space and reach into every corner and into every gap in the available space, determined by the form of the chest cavity into which the lung develops. Some spaces are filled rapidly and the airways cannot continue to divide, whereas in other places more branches are needed to fill the space.

This branching process is accompanied by growth in length and diameter of the airway segments, the tubes between the branching nodes. The length of the tubes is adjusted to cover the distances needed to fill the space homogeneously with endings, whereas the diameter is, grossly speaking, made proportional to the volume of peripheral lung that is supplied by this branch.

Figure 2-36 shows a portion of a cast of the airway tree from a human lung. It is evident that the airways branch by dichotomy and that the length and the diameter of the tubes become gradually reduced with each generation. At first sight, the airway branching seems quite regular, but there is a certain degree of asymmetry in the sense that the two daughter branches differ in length and diameter; in animal lungs asymmetry is more pronounced than in human lungs.

Despite asymmetric branching some general rules govern the progression of dimensions along the tree. The diameter of daughter branches is smaller than that of the parent in the sense that the diameter reflects the volume of peripheral lung it supplies with air: larger airways serve larger lung units, smaller airways smaller units. The progression of airway diameters follows the law of Hess (1917)[158] and Murray (1926)[159] that, in a dichotomous tree, the diameters of the daughter branches, d_1 and d_2, are related to the parent branch d_0 as:

$$d_0^3 = d_1^3 + d_2^3$$

a law that predicts optimization of the airway diameters for convective air flow, providing lowest resistance for lowest dead space.

For a symmetric tree in which $d_1 = d_2$ this becomes:

$$d_1 = d_0 \cdot 2^{-1/3}$$

which means that the airway diameter becomes reduced by a factor of cube root of 1/2 or about 0.79 with each generation. Considering the progression of airway dimensions along the tree, this law should apply to all successive generations so that we predict the average diameter in generation z to be:

$$d(z) = d_0 \cdot 2^{-z/3}$$

Figure 2-37 shows that this is approximately the case for the first 14 generations of conducting airways.

However, a closer look at the airways of the human lung shows that this is only approximately correct.[160] It appears that the smaller bronchioles (beyond generation 10) are provided with some safety factor in that the diameter is reduced by a factor of 0.83 rather than the physically optimal 0.79. This allows regulation of airway cross-section by contraction of the bronchiolar muscle sleeve without unduly increasing flow resistance which is very low in small airways (Fig. 2-38).[161] Design optimization is limited in favor of physiologic robustness.

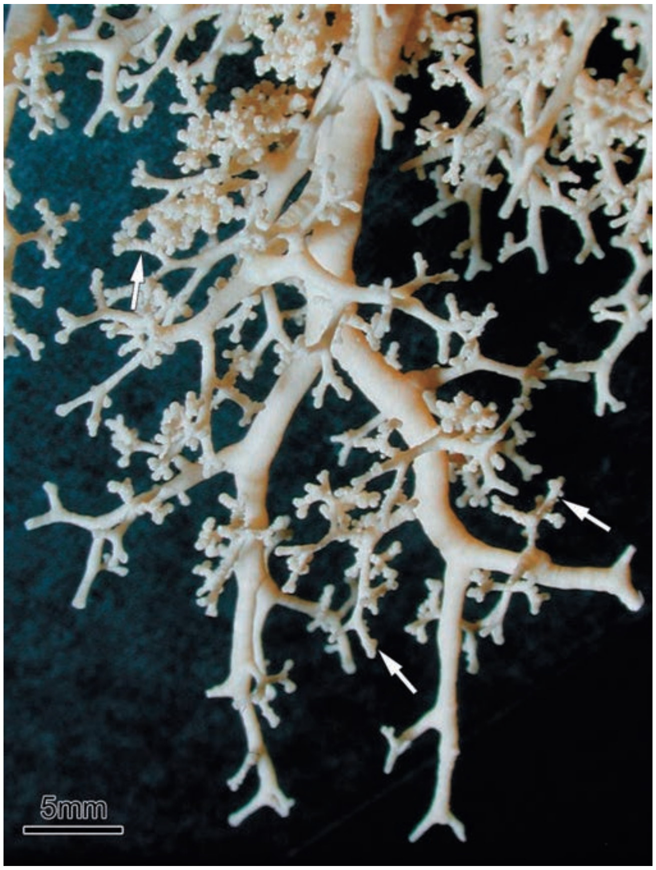

Figure 2-36 Peripheral portion of cast of human airway tree reaching out to the transitional bronchioles and some respiratory bronchioles *(arrows)*.

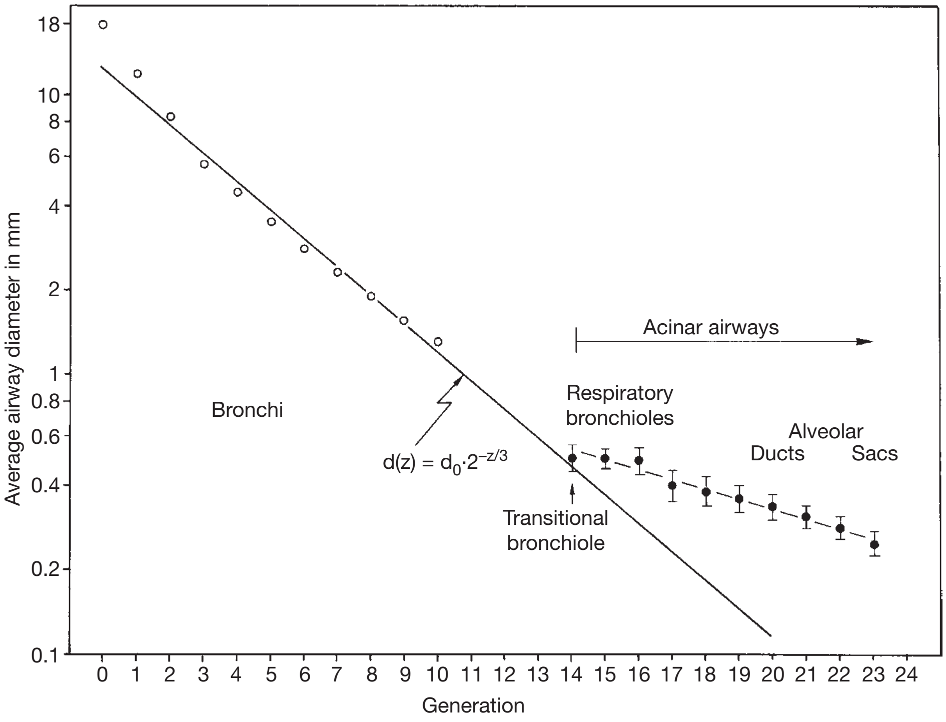

Figure 2-37 Average diameter of airways in human lung plotted by generations of regularized dichotomous branching. *(Reproduced with permission from Haefeli-Bleuer B, Weibel ER: Morphometry of the human pulmonary acinus. Anat Rec. 1988;220(4):401–414.)*

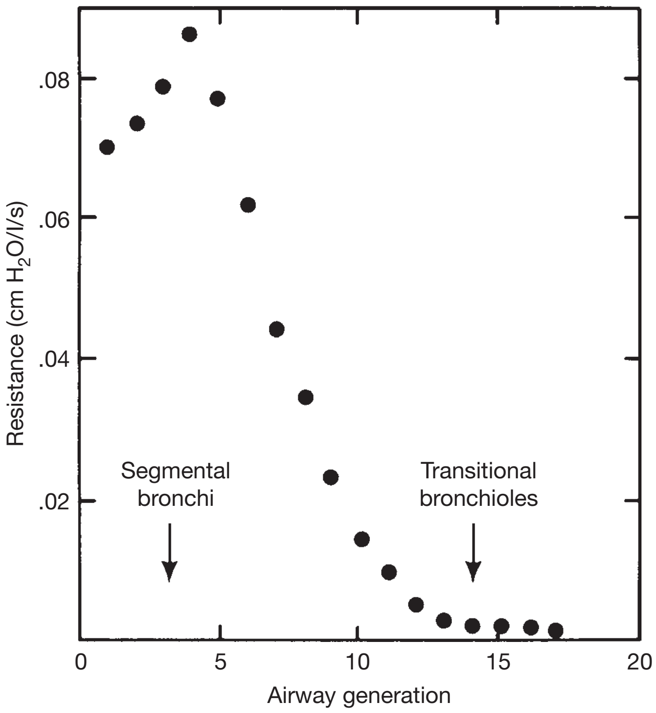

Figure 2-38 Airway resistance to mass air flow is located mostly in the conducting airways and falls rapidly toward the periphery. *(Reproduced with permission from Pedley TJ, Schroter RC, Sudlow MF. The prediction of pressure drop and variation of resistance within the human bronchial airways, Respir Physiol. 1970;9(3):387-405.)*

This symmetric airway model reflects the typical pathway along the airway tree. It has been very useful in modeling the basic rules governing the distribution of air flow as well as the deposition of particles entering the lung. However, it disregards the effects of asymmetric branching. It is possible to construct models that take into account irregularities in branching, for example by considering the number of airways of a given diameter, d_u, that exist in each generation, and the length of the bronchial pathway that intervenes between the larynx and particular airways (Fig. 2-39).[8,162]

An alternative approach is to regard the airways as a system of tubes converging from the periphery, the acinus, toward the center, the trachea.[163] By using an ascending ordering system that is employed in analyzing rivers (Strahler system), branches are grouped into orders according to the sequence of convergence, beginning with the smallest most peripheral branches, designated as order l. This ordering pattern is particularly well adapted to a system of irregular dichotomy because the size of branches in one order varies less than with the generations-down model. This approach does not really account for the asymmetry of branching, however; it rather represents an attempt at extracting average data with less variability in each order. The degree of asymmetric branching is reflected in the branching ratio determined as the ratio of the number of branches in order μ to that in order $\mu + 1$. Remarkably, the progression of diameters through the various orders is again roughly proportional to the cube root of the branching ratio. Hence, from a functional point of view both models yield comparable results.

The general conclusion drawn from this type of analysis is that the diameters of the conducting airways are such as to assure optimal conditions for airflow but relaxing physical optimality conditions in the interest of physiologic robustness; the airways of the lung are thus well designed. The total volume of the conducting airways down to generation 14 (the anatomic dead space) is about 150 mL; it is rapidly flushed by simple gas flow in the course of inhaling 500 mL of fresh air during quiet inspiration. Therefore, for the larger airways, optimization for flow and its distribution to peripheral units are essential for good design.

These are the characteristics of the proximal airways built as smooth-walled tubes to distribute convective air flow into the lung. This design ends more or less abruptly when the airways reach lung parenchyma, the complex of alveoli that are arranged around peripheral airways (Fig. 2-40). The airway tree is thus subdivided into two major functional zones (Fig. 2-5): the first about 14 to 16 generations, on average, are designed as conducting airways where air flow is by convection; this is followed by about 8 generations of acinar airways where an axial channel, called *alveolar duct*, is enwrapped by a sleeve of alveoli with gas-exchange tissue on their surface.

In the human lung the transition is not abrupt. At some point the smooth bronchiolar wall becomes interrupted by one or two alveoli (Fig. 2-41). This so-called *transitional bronchiole* (Fig. 2-5) marks the entrance into an acinus.[9] It is followed by some three generations of respiratory bronchioles where an increasing fraction of the wall surface is occupied by alveoli, until the alveolar ducts are reached where the central air duct is completely surrounded by alveoli (Fig. 2-42). These acinar airways continue to branch by dichotomy. Their length and diameter decrease with each generation, but the slope does not follow the law of reduction by the cube root of 1/2; the diameters of respiratory bronchioles and alveolar ducts change very little with each generation.[9] Does this arrangement imply less than an optimal design? On the contrary, the cube-root-of-1/2 law relates to optimizing mass flow of a liquid or air. In the most peripheral airways, mass airflow is only part of the means of transporting O_2 toward the air–blood barrier. Since the airways are blind-ending tubes and since a sizable amount of residual air remains in the lung periphery after expiration, O_2 molecules must move into the residual air by diffusion (Fig. 2-43). However, diffusion of O_2 in the gas phase is best served by establishing as large an interface as possible between residual air and the fresh air that flows in from the trachea.[16] In fact, since the airway diameter remains nearly unchanged, the total airway cross section nearly doubles with each generation beyond generation 14.

The dimensions of the airway tree influence the ventilatory flow of air in a number of ways. First of all, airflow velocity falls along the airway tree because the total cross-sectional area of the airways increases with every generation (Fig. 2-44); whereas the cross-sectional area of the trachea is about 2.5 cm^2, that of the 1024 airways in the 10th generation taken together is 13 cm^2, and as we approach the acinar airways, the total cross section reaches 300 cm^2. However, since the same air volume flows through all generations, the flow velocity falls by more than 100-fold from the trachea to the acini: at rest, the mean flow velocity on inspiration is about 1 m s^{-1} in the trachea and less than 1 cm s^{-1} in the first-order respiratory bronchioles. In exercise, the flow velocities are up to 10 times greater, in proportion to the increased ventilation. This is discussed further when considering the relative importance of convection and diffusion in bringing O_2 to the alveolar surface for gas exchange.

The size of airways also determines the resistance to airflow. However, the overall resistance is rather small; it is given by the reciprocal of the ratio of ventilatory airflow to the pressure difference between the mouth and alveoli, which is normally no greater than about 1 cmH$_2$O (mbar) or less than 1 mm Hg. It is large enough, however, to potentially affect the distribution of ventilation to the many gas-exchange units. Because, in laminar flow, the resistance is inversely proportional to d^4 the distribution of air flow depends on a delicate balance of the size of parallel airway tracts. Even a slight narrowing of one of the two daughter branches at

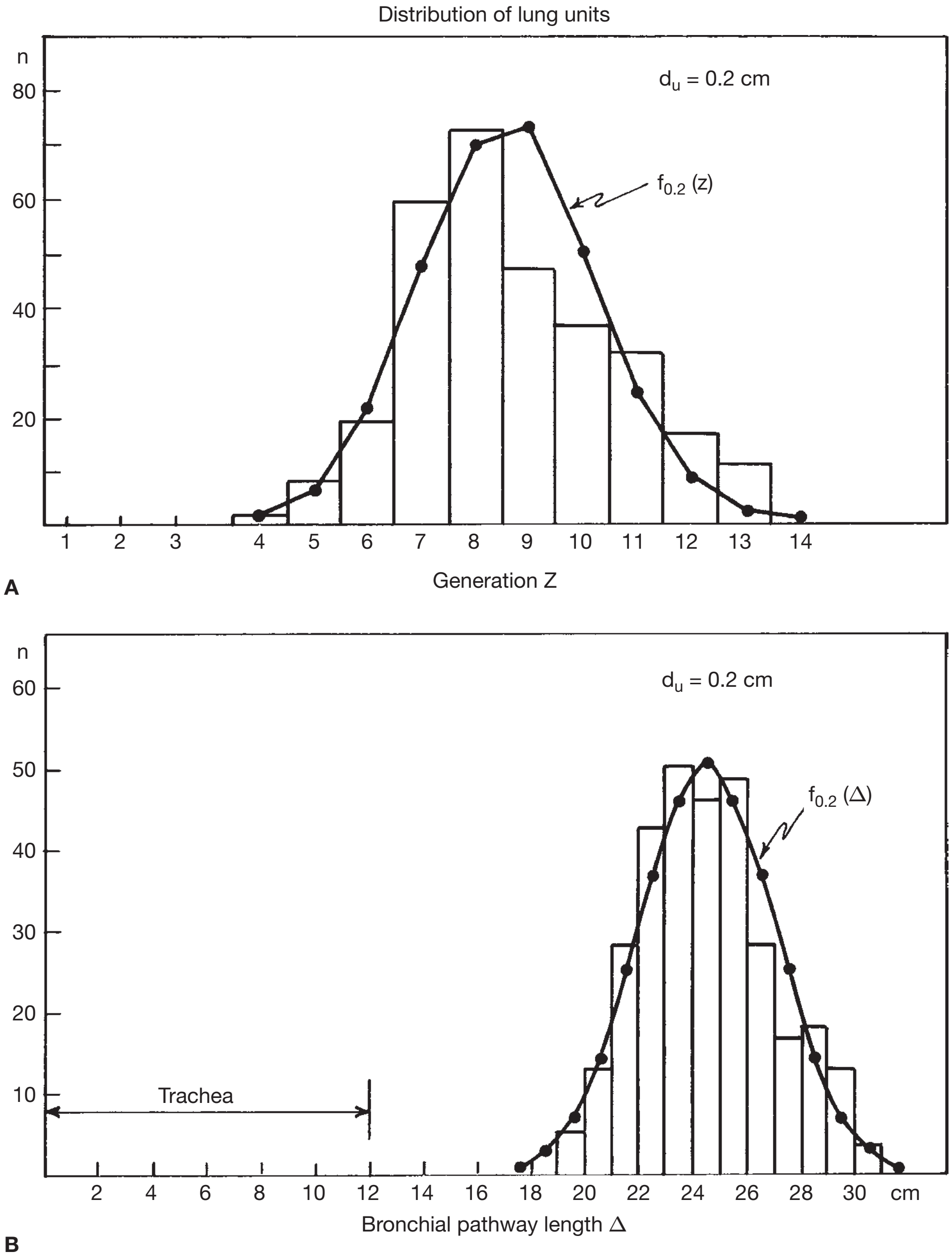

Figure 2-39 Distribution of airways of diameter d_u = 2 mm with respect to (**A**), generations of branching and (**B**), bronchial pathway lengths. *(Reproduced with permission from Weibel ER: Morphometry of the Human Lung. Heidelberg: Springer-Verlag; 1963.)*

a branch point will cause disproportionate air flow to the other branch and thus result in ventilation inhomogeneity.

Since the diameter of airways decreases as they branch (Fig. 2-37), one would suspect that their resistance increases toward the periphery. Apparently, this is not the case, as the major pressure drop along the airways occurs in medium-sized bronchi; because the airway diameter decreases with a factor larger than the optimal 0.79, resistance becomes very low in the small bronchioles (Fig. 2-38).[161] This is further accentuated by the fact that the thin-walled bronchioles become widened as the lung expands on inspiration because they are subject to the tissue tensions in the coarse fiber system of the lung. Therefore, airway resistance is seen to fall as lung volume increases. When this effect of tissue tension is disturbed, as in emphysema, some small bronchioles may collapse. This causes ventilation of the peripheral lung units to become highly uneven.

This biophysical way of looking at the significance of the progression of airway dimensions has recently been complemented by the alternative notion that the airway and vascular trees could be determined by the laws of fractal geometry.[164] Fractal trees are formed by repeating the branching pattern from one generation to the next. If the proportion between parent and daughter branches remain the same this is called *self-similar branching*. In a dichotomous tree the diameter is ideally reduced by a factor of $2^{-1/D_f}$ where D_f is the fractal dimension. Since the airway tree is nearly space-filling $D_f \sim 3$, which means that the Hess–Murray law also follows from fractal geometry as a rule of optimal design, but because the reduction factor is somewhat larger than $2^{-1/3}$ it follows that the actual fractal dimension of the airway tree is a bit larger than 3; this is possible because the tree is "cut off" at the entrance to the acini and the "space" becomes filled with alveoli.[165,166]

■ Design of the Vascular Tree

In many ways, the course and pattern of dimensional changes in the pulmonary blood vessels resemble those of the airways. Figure 2-3 shows that the pulmonary arteries follow the airways closely, out to the smallest branches; together they form the axis of lung parenchymal units of varying order: acinus, lobule, segment,

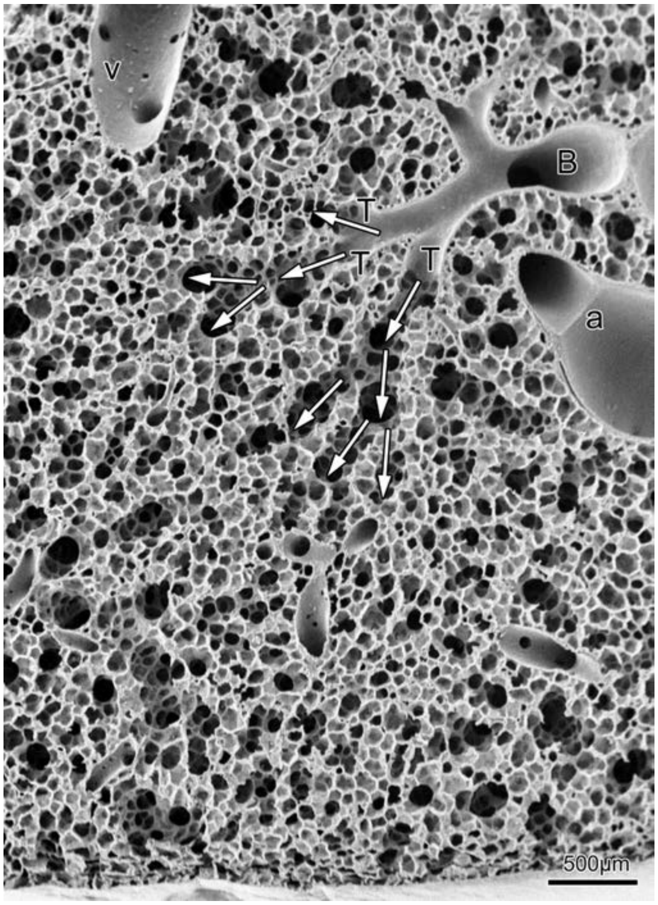

Figure 2-40 Scanning electron micrograph of lung shows branching of small peripheral bronchiole (B) into transitional bronchioles (T), from where the airways continue into respiratory bronchioles and alveolar ducts *(arrows)*. Note the location of the pulmonary artery (a) and vein (v) as well as visceral pleura *(bottom)*.

lobe. As indicated, the veins are differently disposed, lying in the boundary between two or three adjacent units (Figs. 2-30 and 2-45).

The diameter of each pulmonary artery branch also approximates closely that of the accompanying bronchus (Fig. 2-45A). Therefore, it is evident that the diameter law presented earlier for airways must also hold for the first 10 to 16 generations of pulmonary arteries (Fig. 2-37). However, the pulmonary arteries divide more frequently than the airways; very often, small branches leave the artery at right angles and supply blood to the parenchymal units adjacent to the bronchus (Fig. 2-45B). From a count of precapillaries, it seems that the pulmonary arteries divide, on the average, over 28 generations, as compared with 23 for the airways. The diameter of these terminal vessels is about 20 to 50 µm; if this range is plotted onto an extension of the graph of Fig. 2-37 to generation 28, it falls on the curve that is obtained by extrapolation from the major branches[8,16]:

$$d(z) = d_0 \cdot 2^{-z/3}$$

This suggests that the pulmonary arteries abide to the cube-root-of-1/2 law from beginning to end. Evidently, the blood is transported to the capillary bed by mass flow only. Therefore, there is no reason to deviate from this fundamental law of design, which minimizes the loss of energy caused by blood flow.

In a thorough analysis of the pulmonary vascular trees[167] conceived as fractal structures it has been shown that the fractal dimension of both arteries and veins is 2.71, thus somewhat less than 3.

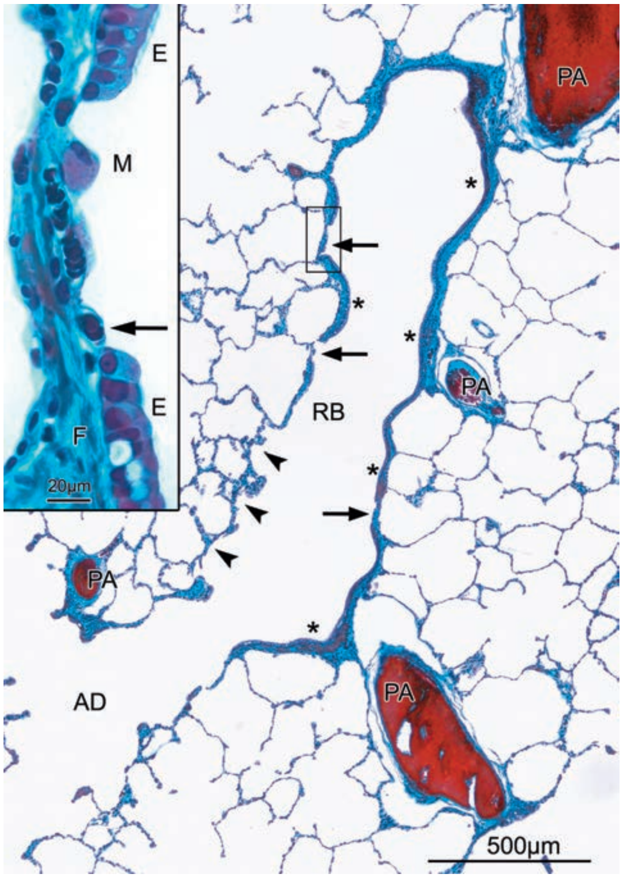

Figure 2-41 Respiratory bronchiole (RB) from human lung cut along its axis toward the transition to alveolar ducts (AD). Note lining by cuboidal airway epithelium *(asterisks)* and the occurrence of respiratory patches *(arrows)* before alveoli proper *(arrowheads)* appear. PA marks branches of pulmonary artery. *Inset:* Higher magnification of one of the respiratory patches in the wall of the respiratory bronchiole with capillaries *(arrow)* and alveolar macrophage (M). The cuboidal epithelium (E) with cilia is replaced by thin squamous epithelium of alveolar type 1 cell. Note thick fibrous layer (F) with smooth muscle cells.

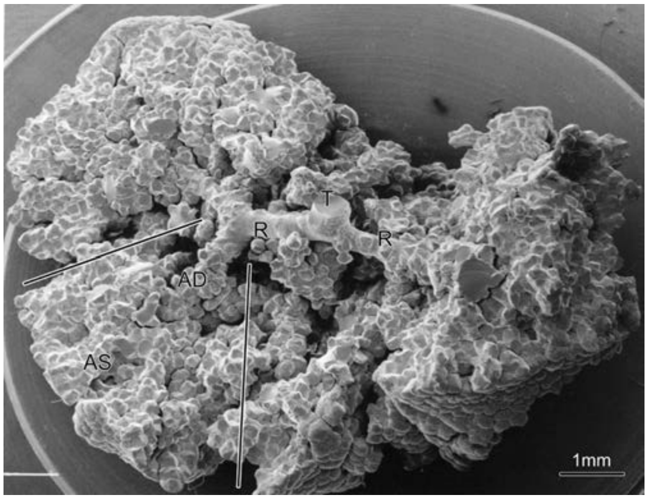

Figure 2-42 Scanning electron micrograph of a complete acinus from a silicon rubber cast of a human lung partly dissected to show transitional (T) and respiratory (R) bronchioles as well as alveolar ducts (AD) and alveolar sacs (AS). Lines mark approximate boundary of 1/8 subacinus. *(Reproduced with permission from Haefeli-Bleuer B, Weibel ER: Morphometry of the human pulmonary acinus. Anat Rec. 1988;220(4):401–414.)*

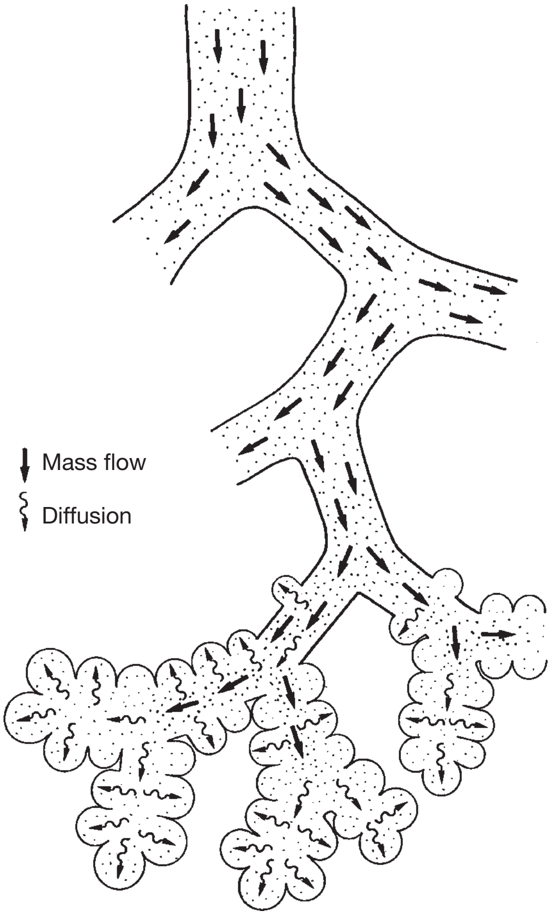

Figure 2-43 Oxygen molecules reach alveoli by combined mass airflow and molecular diffusion, the importance of diffusion increasing toward the periphery.

The diameter reduction factor is therefore slightly smaller than cube-root-of-1/2, and the diameters follow the regression:

$$d(z) = d_0 \cdot 2^{-z/2.71}$$

Therefore, in contrast to the airways, the resistance to blood flow increases along the pulmonary arteries and is highest in the most peripheral branches or arterioles. The resistance profile of the pulmonary arteries is thus the same as in the systemic circulation.

The alveolar capillary network of the lung is very different from that of the systemic circulation. Whereas in muscle, for example, long capillaries are found to be joined in a loose network, the capillaries of the alveolar walls form dense meshworks made of very short segments (Fig. 2-46).[8,168] The meshes are so dense that some people believe blood flows through the alveolar walls like a sheet rather than through a system of interconnected tubes. In this sheet-flow concept,[169] the sheet is bounded by two flat membranes, the air–blood barrier, connected by numerous "posts." When blood flows through this sheet, it is not channeled in a given direction but has freedom to move in a tortuous way between the posts. Although this concept oversimplifies the actual structural conditions, it does provide a useful description of the pattern of blood flow through the alveolar walls and explains why blood flow is not interrupted when some parts of the capillary bed become squashed flat at high inflation levels (see Fig. 2-58); the capillaries that remain open in the corners are simply some channels of this broad sheet. Furthermore, it is important to note that the capillary network or sheet is continuous through many alveolar walls (Fig. 2-46), probably at least throughout the entire acinus, if not for greater distances.[168] Consequently, it is not possible to isolate microvascular units. One finds, rather, that arterial end branches simply feed into this broad sheet at more or less even distances and that the veins drain these sheets in a similar pattern. However, now we must remember that the arteries reach the acinus along the airways, whereas the veins are in a peripheral location (Fig. 2-45). In principle, therefore, blood flows through the acinar capillary sheet from the center to the periphery of the acinar gas-exchange unit.

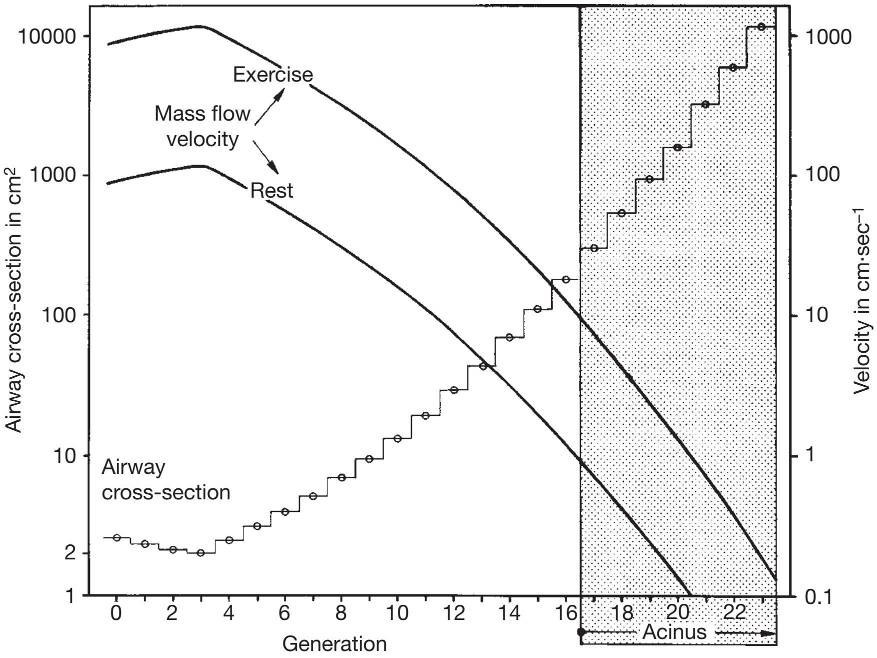

Figure 2-44 As total airway cross-section increases with the generations of airway branching, the mass flow velocity of inspired air decreases rapidly, falling below the molecular velocity of O_2 diffusion in air as we enter the acinus (see Fig. 2-66). *(The Pathway for Oxygen: Structure and Function in the Mammalian Respiratory System by Ewald R. Weibel, M.D., Cambridge, Mass.: Harvard University Press, Copyright © 1984 by the President and Fellows of Harvard College. Used by permission. All rights reserved.)*

DESIGN OF PULMONARY PARENCHYMA

The pulmonary parenchyma is a complex structure, the design of which is considered below.

■ Alveoli and Capillaries

The airspaces and blood vessels of lung parenchyma are designed to facilitate gas exchange between air and blood. To this end a very large area of contact between air and blood must be established; for the human lung it is sometimes compared with the area of a tennis court in size. Furthermore, the tissue barrier separating air and blood must be kept as thin as possible—it is found to be about 50 times thinner than a sheet of airmail stationery. This is important, because less than 1 second is available for loading O_2 onto the erythrocytes as they flow through the lung's gas-exchange region.[170]

The first design feature to this end is the formation of alveoli in the walls of all airways within the acinus—that is, in the ventilatory gas-exchange units beginning with a transitional bronchiole (see above) (Fig. 2-40). In the human lung, one estimates that there are about 30,000 acini,[9] and 400 million alveoli[171]

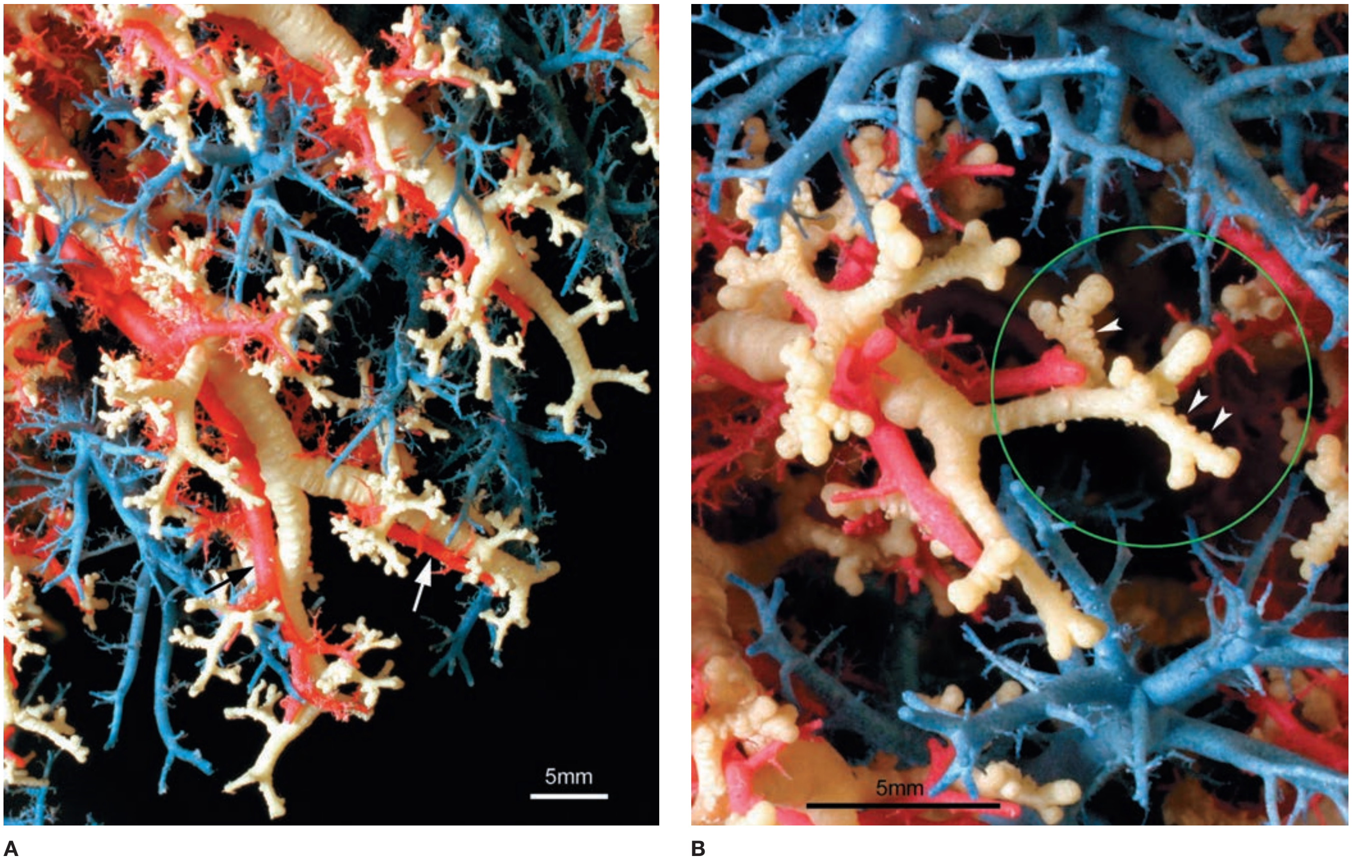

Figure 2-45 Casts of airways and blood vessels of human lung. **A.** shows how the pulmonary artery *(red)* closely follows the airways *(yellow)* to the periphery, whereas the pulmonary vein branches *(blue)* lie between the units. Note that the diameter of the pulmonary arteries is similar to that of the accompanying airway, but becomes relatively smaller toward the periphery *(arrow)*; small supernumerary arteries take off at right angles. **B.** Higher power view of group of acini *(circle)*, corresponding about to a secondary lobule, shows how artery penetrates into center of gas-exchange unit with veins collecting the blood around the periphery. *Arrowheads* point to alveolar pouches on transitional and respiratory bronchioles.

so that each of the ventilatory gas-exchange units contains some 13,000 alveoli, on average, connected to about seven to nine generations of acinar airways, respiratory bronchioles, and alveolar ducts.[9]

The alveoli are so densely packed that they occupy the entire surface of alveolar ducts; they are separated from each other by delicate alveolar septa that contain the capillary network (Fig. 2-47). About half the space of the septum is taken up by blood, which is thus exposed to the air in two adjacent alveoli (Fig. 2-48A). Although the barrier separating air and blood is extremely thin, we find the capillaries to be provided with a complete endothelial lining, as the alveolar surface of the septum is lined by an epithelium.[11] We have seen earlier that these two cell linings are very much attenuated over the greatest part of the surface.

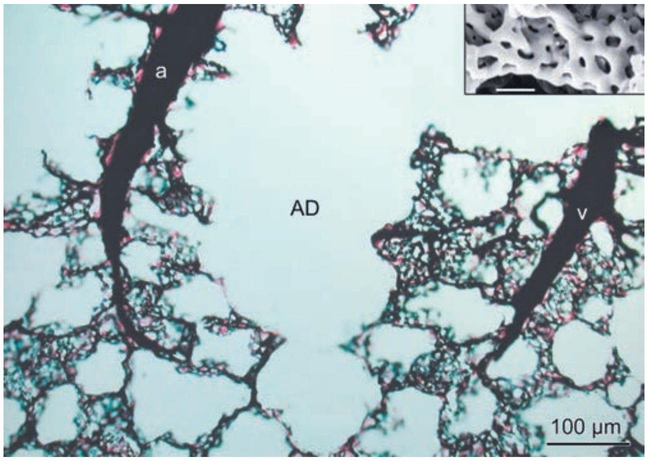

Figure 2-46 Alveolar capillary network demonstrated with gold labeling of blood plasma in a physiologically perfused preparation of a rabbit lung. The dense capillary network spans between end branches of pulmonary artery (a) and vein (v) and extend through many alveolar septa around alveolar duct (AD). *Inset:* Plastic cast shows the dense meshes of the network. Scale bar = 20 µm. *(Inset reproduced with permission from P. Burri.)*

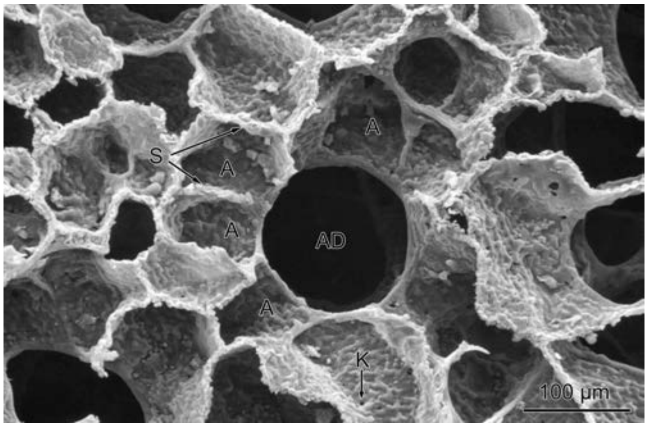

Figure 2-47 Scanning electron micrograph of human lung parenchyma. Alveolar ducts (AD) are surrounded by alveoli (A), which are separated by thin septa (S). K, interalveolar pore of Kohn.

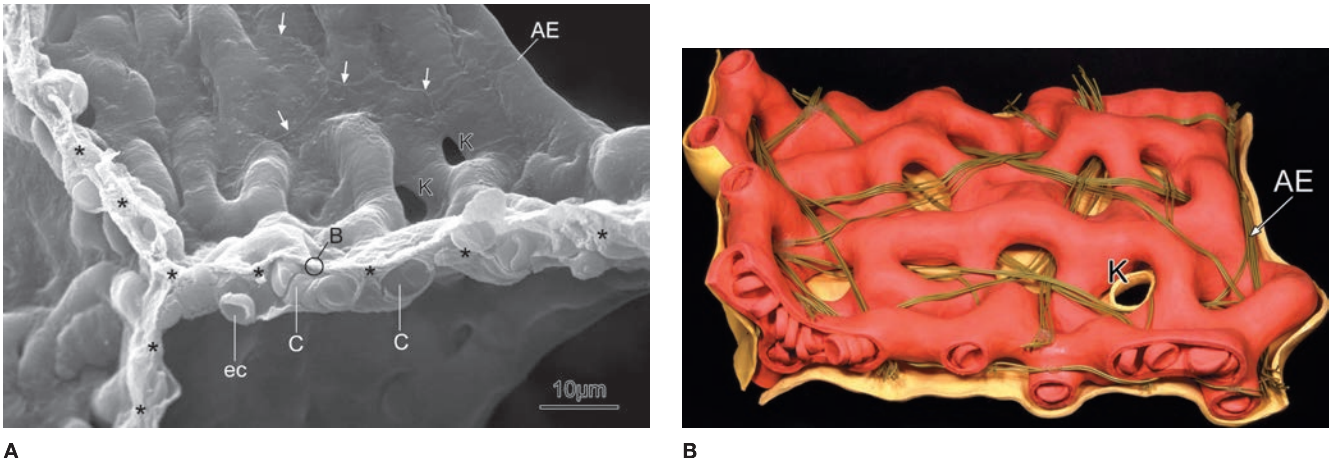

Figure 2-48 In the alveolar wall, shown in (**A**) in a scanning electron micrograph from a human lung, the capillary blood (C) with its erythrocytes (ec) is separated from the air by a very thin tissue barrier (B). *Short arrows* mark intercellular junctions of alveolar epithelium that course toward interalveolar pores of Kohn (K). The model (**B**) shows the capillary network *(red)* to be interwoven with the meshwork of septal fibers *(green)*, the course of which is marked by asterisks in (**A**). The epithelial lining *(yellow)* that crosses the septum at interalveolar pores (K) is removed on the upper surface of the septum to show the capillary. The septal fibers are anchored on the strong fiber bundle marking the free edge of the septum or the alveolar entrance ring (AE). *(The Pathway for Oxygen: Structure and Function in the Mammalian Respiratory System by Ewald R. Weibel, M.D., Cambridge, Mass.: Harvard University Press, Copyright © 1984 by the President and Fellows of Harvard College. Used by permission. All rights reserved.)*

To make the barrier very thin, the interstitial structures must also be reduced to the minimum required (Fig. 2-49). The septal interstitium contains very few cells, mostly slim fibroblast with long extensions; these contain fine bundles of contractile filaments that serve an as yet unknown mechanical function. The septal interstitium usually does not contain cells of the defense system or lymphatics.

■ Internal Support of Parenchymal Structures: The Pulmonary Fiber Continuum

This extraordinary reduction of the tissue mass in the alveolar septa inevitably introduces a number of major problems. How is it possible to secure the mechanical integrity of the system if we consider that several forces act on the septal tissue with a tendency to disrupt it? The thin barrier must not only withstand the distending pressure of the capillary blood due to both hemodynamic forces and gravity, particularly in the lower lung zones, but must also keep the capillary bed expanded over a very large surface—a task that is made difficult because surface forces that act on the complex alveolar surface would tend to collapse alveoli and capillaries (see further below). This requires a very subtle, economical design of the fibrous support system.[172,173]

The problem of supporting the capillaries on connective tissue fibers with as little tissue as possible has been solved ingeniously: we find that the fiber network is interlaced with the capillary network.[174] Figure 2-48B shows that when the fibers are taut, the capillaries weave from one side of the septum to the other. This arrangement has a threefold advantage: (1) it allows the capillaries to be supported unit by unit directly on the fiber strands without the need of additional "binders"; (2) it causes the capillaries to become spread out on the alveolar surface when the fibers are stretched; and (3) it optimizes gas-exchange conditions by limiting the presence of fibers, which must interfere with O_2 flow, to half the capillary surface. The thin section of a capillary shown in Fig. 2-49 reveals that an interstitial space with fibers and fibroblasts exists on only one side of the capillary, whereas on the other the two lining cells, endothelium and epithelium, become closely joined with only a single common basement membrane interposed. Therefore, over half the surface of the capillary blood is separated from the air merely by a minimal tissue barrier made of epithelial and endothelial cytoplasmic sheets with their basement membranes fused leaving no interstitial space that could enlarge with interstitial pulmonary edema (Fig. 2-17).

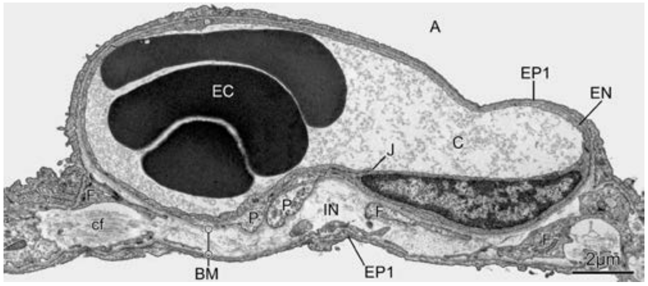

Figure 2-49 Alveolar septum from human lung lined by type I epithelium (EP1) with capillary lined by endothelial cell (EN) that is associated with processes of pericytes (P). Substantial interstitial space (IN) with collagen and elastic fibers (cf) and fibroblasts (F) occurs on one side only, whereas minimal air–blood barrier is formed on other side by fusion of basement membranes (BM) of endothelium and epithelium.

The principal structural "backbone" of the lung is a continuous system of fibers anchored at the hilum and put under tension by the negative intrapleural pressure that tugs on the visceral pleura.[173] The general construction principle follows from the formation of the mesenchymal sheath of the airway units in the developing lung; as the airway tree grows, its branches remain separated by layers of mesenchyme within which blood vessels form. When fiber networks develop within this mesenchyme, they enwrap all airway units and extend from the hilum right to the visceral pleura. The pulmonary fiber system hence forms a three-dimensional fibrous continuum that is structured by the airway system and is closely related to the blood vessels. By virtue of the design of this fibrous continuum, the lung becomes, in fact, subdivided into millions of little bellows that are connected to the airway tree, as represented schematically in Fig. 2-50; these structures expand with expansion of the chest because the tension exerted on the visceral pleura by the negative intrapleural pressure becomes transmitted to the bellows' walls through that fiber system.

To try to put some order into this fiber system, we can first single out two major components that can be identified easily (Fig. 2-50).

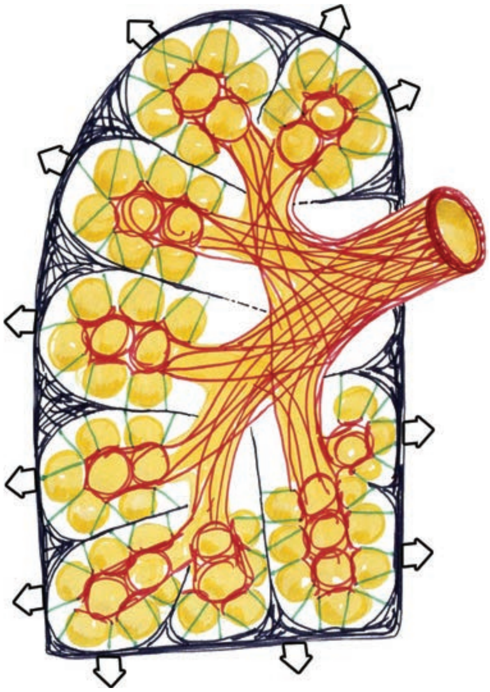

Figure 2-50 The lung's fiber continuum: axial fibers *(red)* extend from airways into the alveolar ducts as a network of entrance rings into alveoli *(yellow)*; peripheral fibers *(black)* extend from the pleura to interlobular septa; the septal fibers *(green)* in the alveolar walls are anchored in peripheral and axial fibers. *Arrows* indicate the traction on the pleura exerted by thorax and diaphragm. *(Reproduced with permission from Weibel ER: Looking into the lung: What can it tell us? Am J Roentgenol. 1979;133(6):1021–1031.)*

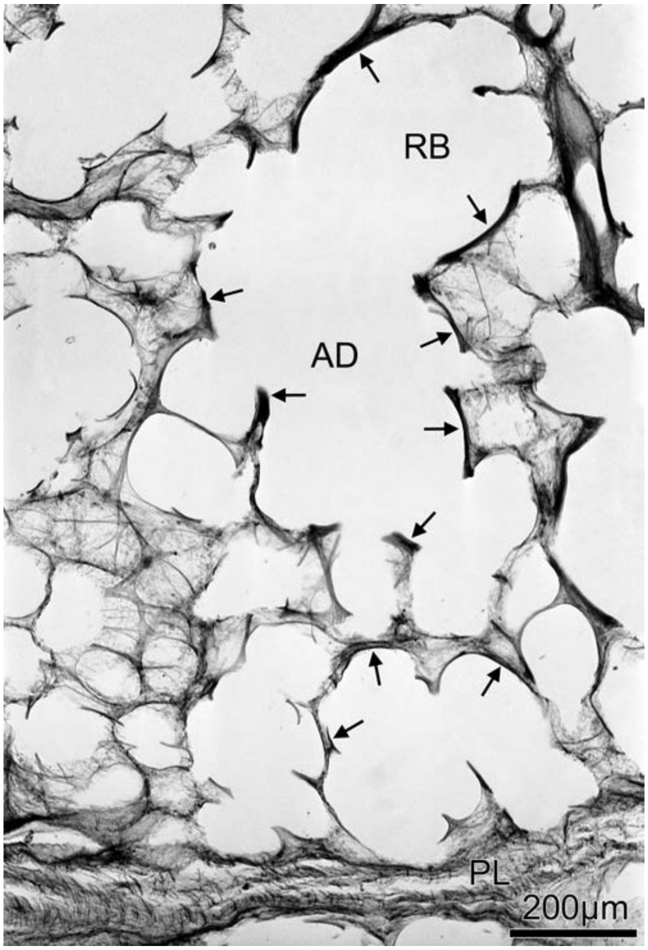

Figure 2-51 Connective tissue stain reveals the strong fiber rings *(arrows)* that demarcate the alveolar ducts (AD) and respiratory bronchioles (RB). Pleura (PL) extends as peripheral fibers into parenchyma. *(The Pathway for Oxygen: Structure and Function in the Mammalian Respiratory System by Ewald R. Weibel, M.D., Cambridge, Mass.: Harvard University Press, Copyright © 1984 by the President and Fellows of Harvard College. Used by permission. All rights reserved.)*

First, we find that all airways—from the mainstem bronchus that enters the lung at the hilum out to the terminal bronchioles and beyond—are enwrapped by a strong sheath of fibers. These fibers constitute the axial fiber system; they form the "bark" of the tree whose roots are at the hilum and whose branches penetrate deep into lung parenchyma, following the course of the airways. A second major fiber system is related to the visceral pleura, which is made of strong fiber bags enwrapping all lobes. We then find connective tissue septa penetrating from the visceral pleura into lung parenchyma, separating units of the airway tree. We call these fibers the peripheral fiber system because they mark the boundaries between the units of respiratory lung tissue.

The peripheral fiber system subdivides the lung into a number of units that are not simple to define because they form a continuous hierarchy in accordance with the pattern of airway tree branching. However, as we have seen, two such units appear to be natural: the lobes, which are demarcated by a more or less complete lining by visceral pleura with a serosal cleft interposed (Fig. 2-1); and the acinus, the parenchymal unit in which all airways participate in gas exchange.

The acinus is the functional unit of the pulmonary parenchyma. The airway that leads into the acinus, the transitional bronchiole, continues branching within the acinus for about 6 to 10 additional generations (Figs. 2-5 and 2-40). These intra-acinar airways, called *respiratory bronchioles* and *alveolar ducts*, also carry in their wall relatively strong fibers of the axial fiber system, which extend to the end of the duct system. However, since the walls of intra-acinar air ducts are densely settled with alveoli, these fibers are reduced to a kind of delicate network that constitutes the "wall" of the alveolar ducts. The meshes of this network that encircle the alveolar mouths are generally called *alveolar entrance rings*; it is this fiber network that allows alveoli to be formed as open chambers with free edges of the alveolar septa (Figs. 2-47 and 2-51).[156] These fiber rings are associated with some smooth muscle cells (Fig. 2-29), and they serve as a scaffold for a network of finer fibers that spread within the alveolar septa (Figs. 2-48B and 2-51). However, in a fiber system there may be no loose ends. Accordingly, the septal fiber system must be anchored at both ends—on the network of axial fibers around the alveolar ducts, and on extensions of the peripheral fibers that penetrate into the acinus from interlobular septa. Thus, the fiber system of the lung becomes a continuum that spans the entire space of the lung, from the hilus to the visceral pleura (Fig. 2-50). It is put under varying tension as the pleural bag is expanded by the chest wall and diaphragm. It thus functions as a tensegrity structure where structural integrity is maintained only if the fiber continuum is under tension and undisrupted.[175,176]

The continuous nature of a well-ordered fiber system is an essential design feature of the lung.[156] This becomes evident in emphysema. When some fibers are disrupted, they cannot be kept under tension. They retract and larger airspaces form as the fiber system is rearranged near the damage. Small foci of emphysema form in most lungs in the course of time.

The fiber system serves mainly as a mechanical support for the blood vessels, with which it is intimately associated in an orderly fashion.[156] The pulmonary artery branches in parallel with the airway tree, but it is not related to the axial fiber system. Like the pulmonary veins the pulmonary arteries are associated with those parts of the peripheral fiber system that form an adventitial sheath on the larger vessels of both types and also form a boundary sheath on the outer surface of bronchi where alveolar complexes touch on the bronchial wall. Therefore, it is justified to characterize the connective tissue surrounding bronchi and pulmonary arteries as a peribronchovascular space, which houses the lymphatics as well as the systemic bronchial arteries and their branches. In fact, this space is continuous with the septal connective tissue that enwraps the pulmonary veins (Fig. 2-30) and is continuous with the visceral pleura. However, whereas the arteries penetrate into the acinus, the veins remain at the periphery and are thus located between the airway units (Fig. 2-45). In the alveolar septa, the capillary network spreads out as a broad sheet of vessels whose paths are continuous throughout the system of interconnected alveolar septa (Fig. 2-46). We have seen that these capillaries are intimately related to the septal fiber system (Fig. 2-48B).

Parenchymal Mechanics and Tissue Design

As in all connective tissue, the fibers of the lung are composed of collagen and elastic fibers.[172] The collagen fibers are bundles of fibrils bound together by proteoglycans; they are practically inextensible (less than 2%) and have a very high tensile strength; they rupture at loads of 50 to 70 dyn/cm^{-2}, which means that a collagen fiber of 1-mm diameter can support a weight of over 500 g. In contrast, elastic fibers have a much lower tensile strength but a high extensibility. They can be stretched to about 130% of their relaxed length before rupturing.

In the fiber system of lung parenchyma, collagen and elastic fibers occur in a volume ratio of about 2.5:1, whereas this ratio is 10:1 for the visceral pleura. In a relaxed state, one finds the collagen fibers to be longer than the accompanying elastic fibers, so that they appear wavy. Because of the association between "rubber-like" elastic and "twine-like" collagen fibers, the connective tissue strands behave like an elastic band. They are easy to stretch up to the point where the collagen fibers are taut, but from there on they resist stretching very strongly.

The elastic properties of the lung's fiber system can be studied by filling the airways with fluid so as to eliminate the effects of surface tension. This reveals that the lung's fiber system has a high compliance until high levels of inflation are reached, and that the retractive or recoil force generated by the fiber system amounts to no more than a few millibars at physiologic inflation levels. The actual recoil force in the air-filled lung, reflected by the negative pressure in the pleural space, is appreciably higher, but this is caused by surface tension rather than the retractive force of the fibers.

Surface tension arises at any gas–liquid interface because the cohesive forces between the molecules of the liquid are much stronger than those between the liquid and gas.[177] As a result, the liquid surface tends to become as small as possible. A curved surface, such as that of a bubble, generates a pressure that is proportional to the curvature and the surface tension coefficient γ. The general formula of Gibbs relates this pressure, P_s, to the mean curvature $\overline{K}$:

$$P_s = 2\gamma \cdot \overline{K}$$

In a sphere, the curvature is simply the reciprocal of the radius r (Laplace's law):

$$P_s = \frac{2\gamma}{r}$$

The most critical effect of surface tension is that it endangers stability of the airspace, because a set of connected "bubbles," the alveoli, is inherently unstable: The small ones should contract and the large ones expand. Since the 400 million alveoli are all connected with each other through the airways, the lung is inherently unstable: Why do the alveoli not all collapse and empty into one large bubble? There are two principal reasons.[16,178,179]

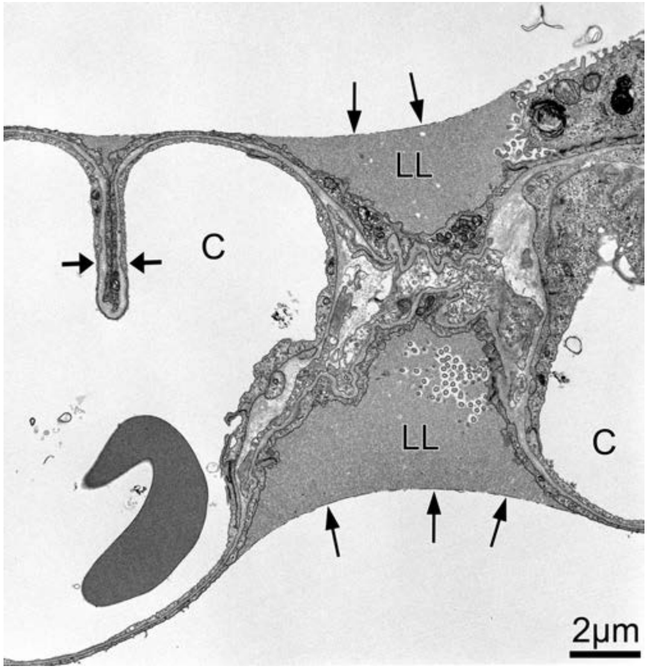

Figure 2-52 Alveolar septum of human lung fixed by perfusion through blood vessels shows alveolar lining layer (LL) in crevices between capillaries (C) topped by surfactant film that appears as a fine black line *(arrows)*. Note the type II cell with lamellar bodies and the fold in thin tissue barrier *(bold arrows)*. *(Reproduced with permission from M. Bachofen and G. Wolff Basel.)*

The first reason is one of tissue structure. The alveoli are not simply soap bubbles in a froth. Rather, their walls contain an intricate fiber system, as we have seen. Thus, when an alveolus tends to shrink, the fibers in the walls of adjoining alveoli are stretched, preventing the alveolus from collapsing altogether. Alveoli are said to be "mechanically interdependent" and, hence, stabilized.

The second reason is related to the fact that the alveolar surface is not simply water exposed to air but is lined by surfactant[180] (Figs. 2-25 and 2-52), which has peculiar properties in that its surface tension coefficient γ is variable.[177,181] From a large volume of evidence, it is now established that surface tension falls as the alveolar surface becomes smaller, and that it rises when the surface expands. Because of this feature, which is due to the phospholipoprotein nature of alveolar surfactant (see above), alveoli do not behave like soap bubbles whose surface tension remains constant. When an alveolus begins to shrink, the surface tension of its lining layer falls and the retractive force generated at the surface is reduced or even abolished. Combined with interdependence, this property of surfactant allows the complex of alveoli to remain stable.[178]

Which of the two factors for stabilizing lung structure is now the most important: interdependence or surfactant properties? It turns out that both are essential. If one depletes the lung of its surfactant lining by washing with a detergent, the pressure–volume curve changes dramatically[182] (Fig. 2-53). On deflation, lung volume falls rapidly. If we look at samples from lungs fixed at the same volume (60% total lung capacity) but derived from either normal or detergent-rinsed lungs, we find that surfactant depletion causes the alveoli to collapse. However, this causes the alveolar ducts to enlarge, stretching the strong fiber nets at the mouths of the collapsed alveoli. The ducts do not collapse because of interdependence between adjacent units.

In the normal air-filled lung, surfactant properties and interdependence owing to fiber tension both contribute to stabilizing

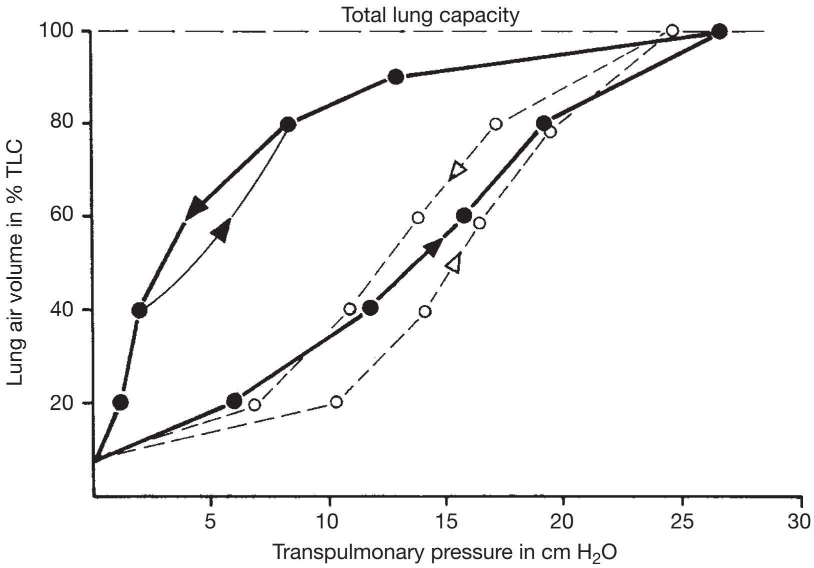

Figure 2-53 Comparison of pressure–volume curve of a normal air-filled rabbit lung *(heavy line)* with that of a surfactant-depleted lung *(broken line)*. The thin line with *paired arrows* represents small hysteresis when breathing between 40% and 80% TLC along the deflation curve.

the complex of alveoli and alveolar ducts.[183] To understand this, let us examine Fig. 2-54, which shows a highly simplified diagram of a parenchymal unit. Interdependence is established by the continuum of axial, septal, and peripheral fibers. Surface tension exerts an inward pull in the hollow alveoli, where curvature is negative. However, over the free edge of the alveolar septa, along the outline of the duct, the surface tension must push outward because there the curvature is positive.[16] The latter force must be rather strong, because the radius of curvature is very small on the septal edge; but this force is counteracted by the strong fiber strands, usually provided with some smooth muscle cells, that we find in the free edge of the alveolar septum (Figs. 2-29, 2-47, and 2-51). Thus, interdependence is an important factor in preventing the complex hollow of the lung, where negative and positive curvatures coexist, from collapsing. However, its capacity to do so is limited and requires low surface tensions, particularly on deflation when the fibers tend to slack. If surface tension becomes too high, the lung's foam-like structure will partly collapse in spite of fiber interdependence.

This is of considerable physiologic importance. It is sometimes claimed that alveoli pop open when the lung is inflated, collapsing on deflation. That is correct when starting with a deflated lung (Fig. 2-53): collapsed alveoli open up along the inflation curve. But that is not the way we breathe. The normal breathing cycle operates on the deflation slope of the pressure–volume curve (Fig. 2-53) with small hysteresis, a state that is maintained by taking a deep sigh intermittently up to TLC. In this condition the surface tension is kept low because the surfactant lining is spread out[181] and alveoli do not collapse. When we breathe in and out between 80% and 40% of total lung capacity, the range of normal breathing in exercise, alveoli change their size very little. In contrast to the twofold change in air volume the alveolar surface area changes by only about a factor of 1.2.[183] The reason for this is that the main change in air volume does not occur in alveoli, but predominantly in the alveolar ducts as shown in Fig. 2-55, and this is very favorable for acinar ventilation. This differential volume change can be explained by the effect of surface forces: at 40% TLC surface tension γ is nearly 0 but it increases to 12 $mN{\cdot}m^{-1}$ at 80% TLC 2. As the lung inflates this causes the positive surface force to become strong on the free edge of alveolar septa (Fig. 2-54), thus causing the duct cross section to widen, while shrinking when the forces decrease on deflation (Fig. 2-55). In this process the alveolar septa become stretched on inflation by only a small degree, a mere 20% in area. The acinus is thus well ventilated whereas the gas-exchange surface is little affected by varying air volume.[156]

■ Micromechanics of the Alveolar Septum

Finally, we must consider the mechanical factors that shape the alveolar septum in the air-filled lung. As we have seen, the alveolar septum is made of a single capillary network that is interlaced with fibers (Fig. 2-48). When the fibers are stretched, the capillaries bulge alternatingly to one side or the other, and this causes pits and crevices to occur in the meshes of the capillary network.

This irregular surface is to some extent evened out by the presence of an extracellular layer of lining fluid, which is rather thin over the capillaries but forms little pools in the intercapillary pits (Fig. 2-52).[184] This lining consists of an aqueous layer of variable thickness, called the *hypophase*, and surfactant, which forms a film on the surface of the hypophase. The hypophase seems to contain considerable amounts of reserve surfactant material, which occurs in a characteristic configuration called *tubular myelin* (Figs. 2-25 and 2-26).

Note that the size of the alveolar ducts (d) is markedly enlarged in 80D due to the surface forces acting on the free edges of alveolar septa *(arrowheads). (Reproduced with permission from H. Bachofen, University of Bern.)*

In the alveolar septum, the tissue structures are extremely delicate, as we have seen. Therefore, its configuration is not exclusively determined by structural features but results from the molding effect of various forces that must be kept in balance. Figure 2-56 shows how the three principal mechanical forces—tissue tension, surface tension, and capillary distending pressure—interact in the septum.[16] The fibers of the alveolar septum are under a tension whose magnitude depends on the level of lung inflation. This tends to straighten out the fibers, so that a force (pressure) normal to the fiber axis results, which is responsible for shifting the capillaries to one side of the septum or the other (Figs. 2-48B and 2-56). The walls of the capillaries are exposed to the luminal pressure, which is the result of blood pressure in pulmonary arteries and veins but also depends on gravity, for one finds wider capillaries at the bottom of the lung than at the top. If this distending pressure acts homogeneously over the circumference of the capillary, it will push against the fibers on one side but will cause the thin barrier on the opposite side to bulge outward. This effect is to some extent counteracted by surface tension, which exerts a force normal to the surface (Fig. 2-56). This force depends on two factors. Its direction depends on the orientation of curvature, acting toward the alveolar space over concave regions (negative curvature) and toward the tissue over convexities (positive curvature); and its magnitude depends on the degree of curvature and on the value of the surface tension coefficient γ.

The alveolar septum achieves a stable configuration when all these interacting forces are in balance.[185] Combined forces tend to squash the capillary flat; this happens at high levels of lung inflation when the fibers are under high tension and the surface tension coefficient of surfactant reaches its highest value because of expansion of the surface. On deflation, the fibers are relaxed, and surface tension falls drastically. The capillary distending pressure now exceeds both the tissue and the surface forces, with the result that the slack fibers are bent, weaving through the capillary network, whereas the capillaries bulge slightly toward the airspace. Surface tension is apparently so low as to permit a considerable degree of surface "crumpling" to persist (Fig. 2-57).

The importance of the balance between the forces that act on the septum is also shown in Fig. 2-58.[186] The specimen of panel B was fixed under zone 3 perfusion conditions, where capillary pressure is larger than alveolar pressure, and all the capillaries are wide, partly bulging toward the airspace, as in Fig. 2-57. This is different in panel A, which was fixed under zone 2 conditions where capillary pressure is close to alveolar pressure. In the flat part of the septum, the capillaries are squashed flat, because the surface and tissue forces now exceed the vascular distending pressure. However, it is interesting that the capillaries remain wide in the corners where three septa come together. The distribution of surface forces causes the internal pressure to be lower in the region of these corners, as we can see intuitively from Fig. 2-54.

■ The Lung as Gas Exchanger

The structures discussed so far are designed to ultimately serve the lung's main function, gas exchange between air and blood, in relation to the body's varying O_2 needs.[187,188] These are set by the energetic demands of the cells and their mitochondria when these produce ATP by oxidative phosphorylation to allow the cells to do work. This process requires a flow of O_2 to be maintained from the lung to the cells, as will be discussed later. It proceeds along the respiratory system through various steps: into

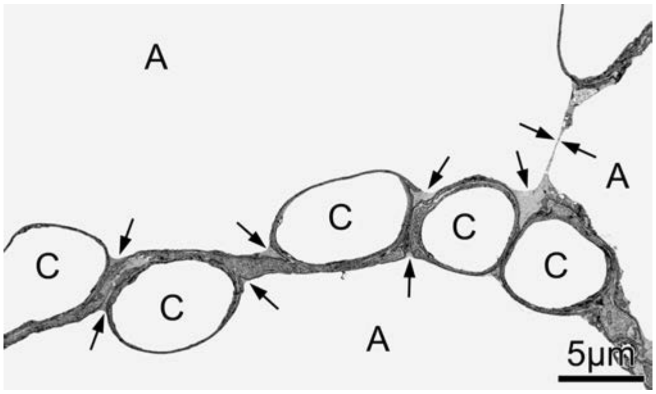

Figure 2-57 Alveolar septum of air-filled rabbit lung perfusion fixed at 60% TLC shows empty capillaries (C), which bulge toward the alveolar airspace (A). Note pools of surface lining layer in the crevices between capillaries *(arrows)* and film spanning across alveolar pore *(double arrows). (Reproduced with permission from Gil J, Bachofen H, Gehr P, et al. Alveolar volume-surface area relation in air- and saline-filled lungs fixed by vascular perfusion. J Appl Physiol Respir Environ Exerc Physiol. 1979;47(5):990–1001.)*

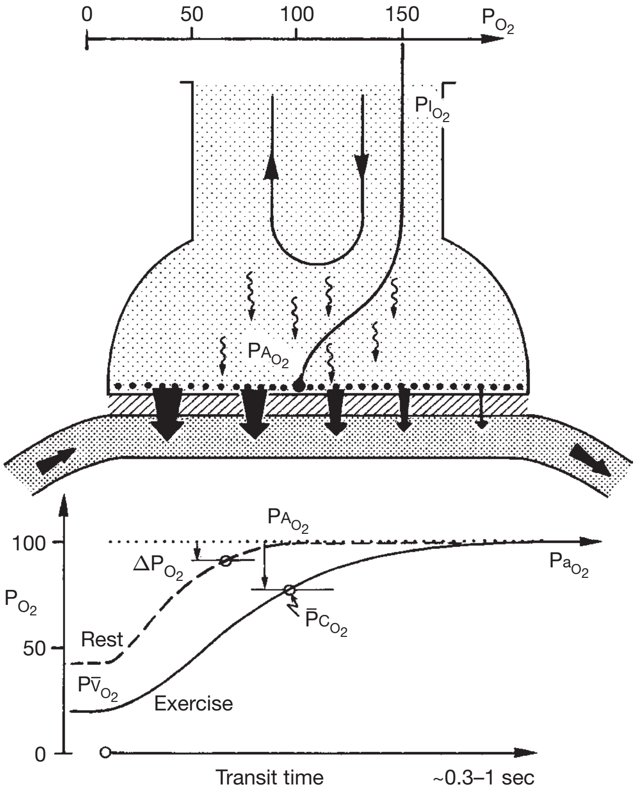

Figure 2-59 Model of gas exchange showing gradual rise of capillary P_{O_2} ($P_{c_{O_2}}$) as blood flows through capillary until it approaches alveolar P_{O_2} ($P_{A_{O_2}}$). *(The Pathway for Oxygen: Structure and Function in the Mammalian Respiratory System by Ewald R. Weibel, M.D., Cambridge, Mass.: Harvard University Press, Copyright © 1984 by the President and Fellows of Harvard College. Used by permission. All rights reserved.)*

the lung by ventilation, to the blood by diffusion, through the circulation by blood flow, from the blood capillaries by diffusion to the cells and mitochondria, where it disappears in the process of oxidative phosphorylation.[16] A number of basic features characterize this system[189]: (1) under steady-state conditions the O_2 flow rate, $\dot{V}_{O_2}$ is the same at all levels, that is, O_2 uptake in the lung is equal to O_2 consumption in the tissues; (2) the basic driving force for O_2 flow through the system is a cascade of O_2 partial pressure which falls from inspired P_{O_2} down to near zero in the mitochondria; (3) the O_2 flow rate at each step is the product of a partial pressure difference and a conductance which is related to structural and functional properties of the organs participating in O_2 transfer, as will be discussed below in detail.

With respect to gas exchange in the lung (Fig. 2-59), the O_2 flow rate is determined by the Bohr equation:[190]

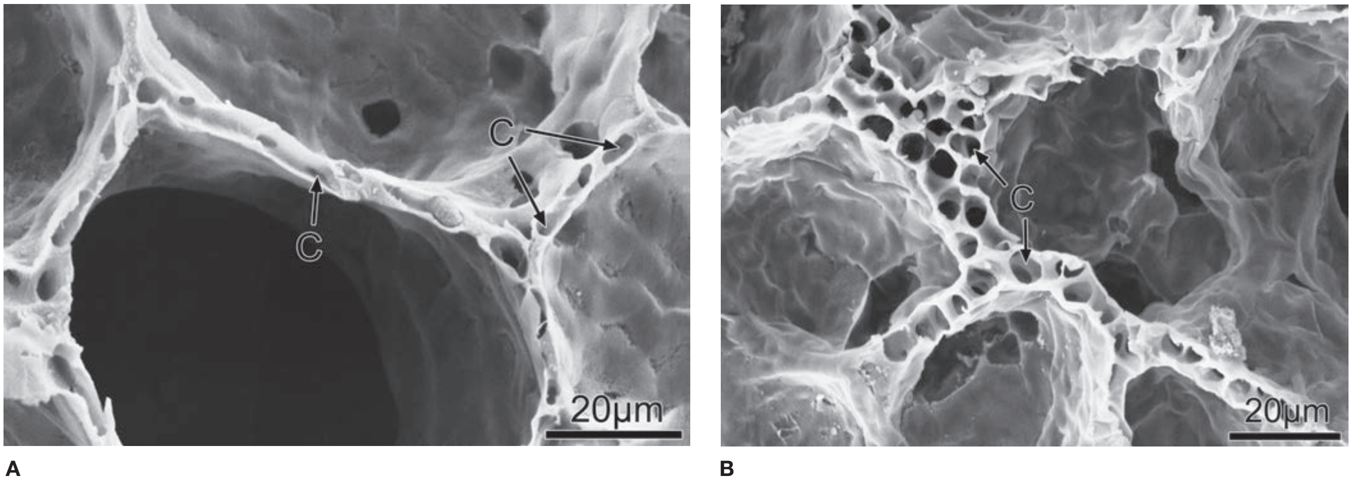
$$\dot{V}_{O_2} = (P_{A_{O_2}} - P\bar{c}_{O_2}) \cdot D_{L_{O_2}}$$

where

$P_{A_{O_2}}$ = P_{O_2} in alveoli,

$P\bar{c}_{O_2}$ = the mean P_{O_2} in pulmonary capillaries, and

$D_{L_{O_2}}$ = the pulmonary diffusing capacity or the lung's O_2 conductance



A **B**

Figure 2-58 Scanning electron micrographs of alveolar walls of rabbit lungs fixed under (**A**), zone 2 and (**B**), zone 3 conditions of perfusion. Note that capillaries (C) are wide in zone 3 and slit-like in zone 2, except for "corner capillaries," which are wide in either case. *(Reproduced with permission from Bachofen H et al. Morphometric estimates of diffusing capacity in lungs fixed under zone II and zone III conditions. Respir Physiol. 1983;52(1):41–52.)*

The important point is now that all parameters to the right of this equation may be significantly affected by design features. We will see that DL_{O_2} is largely determined by the surface area and the thickness of the air–blood barrier. The O_2 partial pressure difference is established by ventilation and perfusion of the gas-exchange units, and this may be affected by the design of the airway and vascular trees, particularly in the acinus.[187]

■ Pulmonary Diffusing Capacity

In the equation mentioned earlier, DL_{O_2} is the total conductance of the gas exchanger for O_2 diffusion from the alveolar air into the capillary erythrocytes until it is bound to hemoglobin. It can be estimated physiologically if we can measure O_2 uptake $\dot{V}_{O_2}$ and estimate the effective P_{O_2} difference between alveolar air and capillary blood, not a trivial undertaking as the change in capillary P_{O_2} as O_2 is being taken up must be integrated (Fig. 2-59). On the other hand, the conductance is a physical characteristic. Therefore, it should be possible to calculate a theoretical value of DL_{O_2} from the physical properties of the gas exchanger, its dimensions and material properties.[191,192] To do that we must consider the geometry of the structures involved, alveoli, tissue barrier, and capillary blood, in setting up a physical model of DL_{O_2}. In the first step, we can break the process into two steps (Fig. 2-60):[193] (1) O_2 flow across the barrier or what has been called the *membrane conductance* DM_{O_2} and (2) O_2 binding to hemoglobin in the red blood cells or the conductance of capillary blood De_{O_2}. These two conductances are in series. Accordingly, their overall effect on O_2 flow is obtained by adding their resistances or the reciprocal of the conductance:

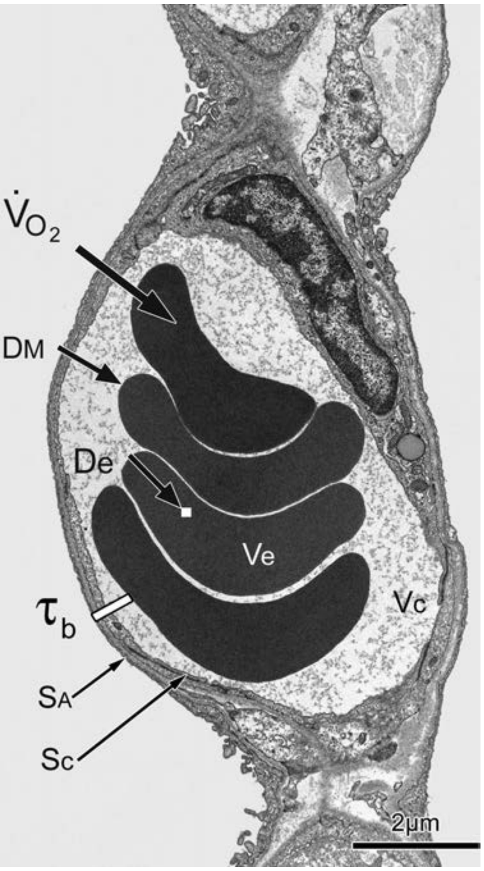


Figure 2-60 Morphometric model for calculating diffusion capacity, DL. Its two components are: (1) the membrane conductance DM, which extends from the alveolar surface (SA) to the nearest erythrocyte membrane traversing the tissue barrier, the capillary surface (Sc), and the plasma layer over the distance τ_b; and (2) the conductance of the erythrocyte interior, De, that depends on the capillary and the erythrocyte volume, Vc and Ve. (See text.)

$$1/DL_{O_2} = 1/DM_{O_2} + 1/De_{O_2}$$

The two conductances DM_{O_2} and De_{O_2} are of very different natures. DM_{O_2} is the conductance of a diffusion barrier that offers "passive" resistance to diffusion and thus depends essentially on the material properties of the barrier, estimated by a diffusion coefficient K, and on the dimensions of the barrier. The larger the surface area S and the thinner the barrier thickness τ the greater DM_{O_2}, according to the formula $DM_{O_2} = K \cdot S/\tau$. In contrast, De_{O_2} is related to a more complex process that involves, besides diffusion, the binding of O_2 to hemoglobin, which is a nonlinear process.

The Membrane Conductance (DM_{O_2})

The structural characteristics of the membrane conductor are seen in Fig. 2-60. It is made of the two layers that separate air in alveoli from the erythrocytes in the capillary: the tissue barrier and the layer of blood plasma. In addition, an alveolar lining layer of varying thickness spreads over the epithelial surface. Even though these layers have distinct characteristics; in effect they act as a single diffusion barrier.[192]

As discussed earlier in this chapter, the tissue barrier is a complex structure. Its two bounding surfaces are formed by independent cell layers, epithelium and endothelium, and they are related to two independent functional spaces, alveoli and capillaries. The two surfaces are not perfectly matched, and the thickness of the barrier varies considerably (Fig. 2-60). Over about half the surface the tissue barrier shows minimal thickness compatible with an intact structure: The thin cytoplasmic leaflets of type I epithelial cells are joined to the thin extensions of endothelial cells by the fused basement membranes leaving no interstitial space. In this region we also find the surface lining layer to be very thin. Over the other half the barrier is thicker because of the occurrence of supporting connective tissue fibers (Fig. 2-49) and the presence of cell bodies of epithelial and endothelial cells as well as fibroblasts, and the lining layer can form deeper pools (Fig. 2-52).

The plasma layer shows even greater variation in its thickness and distribution. Since erythrocytes are of about the same dimension as the capillaries, the plasma layer that separates them from the endothelium can be vanishingly thin where the red cell nearly touches the wall. However, erythrocytes are corpuscular particles and there are "plugs" of plasma of varying size that separate them in the direction of blood flow. Also, their distortable disk shape causes the plasma layer between erythrocyte and capillary surface to be quite variable.[194] Furthermore, occasional leukocytes function like plasma plugs in regard to O_2 diffusion to the red cells. Therefore, the diffusion distance from the capillary wall to the red cell membrane can vary from a few nm to several μm.

Strictly speaking, these two layers of the barrier offer O_2 diffusion different resistances so their conductances should be calculated separately. However, this distinction does not appear to be important under normal conditions. Indeed, it is more reasonable to treat them as a single barrier. For one, the flow velocity of the plasma layer is much lower than the diffusion of O_2 so that plasma is quasistatic with respect to diffusion. Furthermore, under normal conditions the surface areas of alveoli, capillaries, and erythrocytes do not differ much, and the diffusion coefficients of tissue and plasma also are quite similar. Therefore, we prefer now to estimate the membrane diffusing capacity by considering O_2 diffusion from the alveolar surface to the erythrocyte membrane as:[192]

$$DM_{O_2} = K_b \cdot S(b)/\tau_{hb} = K_b \cdot (S(A) + S(c))/2 \cdot \tau_{hb}$$

where K_b is Krogh's permeation coefficient estimated at 3.3×10^{-8} $cm^2\ min^{-1}\ mm\ Hg^{-1}$, τ_{hb} is the harmonic mean distance from the alveolar surface to the nearest erythrocyte membrane, and S(b) is the surface area of the barrier that we estimate as the mean of the alveolar and capillary surface areas, S(A) and S(c), respectively, the two most robust measures of the area of air–blood contact. These parameters can be estimated on sections of properly sampled lung tissue by stereologic methods.[195–197]

We should also mention that the presence of a surface lining layer in the living lung may modify the geometry of the barrier as we see it on electron micrographs with the consequence that both the barrier thickness and the alveolar surface are reduced to a similar degree because some thicker parts of the barrier become shifted beneath the surfactant pools (Fig. 2-52).[186] Therefore, the effect on the estimate of DL_{O_2} is negligible.

Erythrocyte Conductance (De_{O_2})

As mentioned, the erythrocyte conductance is of a different nature in that it involves two coupled events,[193] that is, diffusion of molecular oxygen and oxyhemoglobin within the red blood cell as well as the chemical reaction of O_2 with hemoglobin. A way out of this is to obtain an empirical estimate of the rate at which O_2 is bound to whole blood, θ_{O_2}, and to express the erythrocyte conductance De_{O_2} as:

$$De_{O_2} = \theta_{O_2}\,Vc$$

where Vc is the total capillary blood volume, which can again be estimated on sections by stereologic methods.

The coefficient θ_{O_2} is estimated in vitro on whole blood, but this is difficult because of the effect of variable unstirred layers around the red cells.[198,199] In addition, θ_{O_2} depends on the hematocrit or hemoglobin concentration, and it is not a constant as it falls with increasing O_2–hemoglobin saturation; recent studies have shown that, as blood moves through alveolar capillaries, θ_{O_2} falls gradually from about 4 to 1 mL O_2 mL^{-1}, $torr^{-1}$ so that the correct value can only be found after Bohr integration of capillary P_{O_2}. For normal human lungs and a hemoglobin content of 15 g/100 mL of blood, a value $\theta_{O_2} = 1.8$ $mLO_2 \cdot mL^{-1}$ is a reasonable estimate, but if the actual hemoglobin concentration [Hb] varies a corrected value can be obtained by multiplying this standard value with a factor c = [Hb]/15.

Morphometry of the Human Lung and Diffusing Capacity

With this model in hand, we can now attempt to estimate the diffusing capacity of the human lung on the basis of morphometric data, as listed in Table 2-4. These data, obtained by electron microscopic morphometry on seven young adults,[200] reveal the alveolar surface area to amount to 130 m^2 and the capillary surface to be about 10% smaller. These values are higher than those most commonly quoted in textbooks derived from light microscopic studies, which did not adequately resolve the alveolar surface texture. The harmonic mean thickness of the tissue barrier is 0.6 μm, whereas the total barrier, from alveolar to red cell surface (Fig. 2-60), measures 1.11 μm.[192] The capillary volume is estimated at about 200 mL. With these data we calculate DL_{O_2} for the adult human lung to be about 150 to 200 mL O_2 min^{-1} mm Hg^{-1}, the variation depending on the choice of θ_{O_2}.

These data also allow us to ask how the resistance to O_2 diffusion is distributed between the diffusion barrier and the red cells. Table 2-4 shows that the diffusion conductance of the "membrane" and that of the red cells are very similar, which means that the resistance to O_2 uptake is nearly equally divided between membrane and red cells.

These morphometric estimates of the diffusing capacity are based on model assumptions that are considered reasonable. The test of their validity must be to compare them with physiologic estimates. The standard physiologic value of DL_{O_2} in a healthy adult at rest is about 30 mL O_2 min^{-1} mm Hg^{-1}; thus, considerably less than what we find on the basis of morphometric estimates. However, this is not a valid comparison, because, under resting conditions, we take up only one-tenth the amount of O_2 that our lungs are capable of absorbing under conditions of heavy work. There have been a number of estimates of DL_{O_2} in exercising humans,[201] and these have yielded values of the order of 100 mL O_2 min^{-1} mm Hg^{-1}. This estimate should come closer to the "true capacity" of the lung for O_2 transfer to the blood than the value obtained at rest. The fact that this is only about 50% lower than the morphometric estimate is not disturbing, for we do not know whether the "true diffusing capacity" is completely exploited even in heavy exercise. Inhomogeneities in the distribution of ventilation and perfusion would, for example, limit the degree to which "true" DL_{O_2} can be exploited. One aspect of this type of limitation is discussed in the following when we consider the effect of the acinus design on gas exchange.

TABLE 2-4 Morphometric Estimate of DL_{O_2} for Young, Healthy Adult Humans of 70-kg Body Weight, Measuring 175 cm in Height

Morphometric data (mean ± 1 SE)			
Total lung volume (60% TLC)	4340	±285	mL
Alveolar surface area	130	±12	m^2
Capillary surface area	115	±12	m^2
Capillary volume	194	±30	mL
Air–blood tissue barrier thickness			
Arithmetic mean	2.2	± 0.2	μm
Harmonic mean	0.62	±0.04	μm
Total barrier harmonic mean thickness	1.11	± 0.1	μm
Diffusing Capacity (mL/min/mm Hg)			
Membrane	DM_{O_2}	350	
Total	DL_{O_2}	158

To test whether the morphometric estimate of DL_{O_2} is reasonable we performed, some years ago, a combined physiologic and morphometric estimation of pulmonary diffusing capacity on four species of canids ranging from 4 to 30 kg in body mass.[202]

Because it is difficult to estimate mean capillary P_{O_2} reliably, most physiologic measurements of the diffusing capacity use carbon monoxide (CO) as a tracer gas; CO binds to hemoglobin so avidly that, for practical purposes, the Pb_{CO} is zero, so that it suffices to measure CO uptake and alveolar CO concentration. It is also possible to revise the morphometric model of diffusing capacity to estimate the conductance for CO instead of O_2 by appropriately changing the permeability coefficients and the rate of CO binding to erythrocytes, θ_{CO}, whereas the morphometric parameters are not changed. In a study on dogs and on other canids, the calculated morphometric value of DL_{O_2} was found to be larger than the physiologic estimate by less than a factor of 1.5, thus confirming the observation made with respect to human lungs.

Therefore, we conclude that the pulmonary gas exchanger is designed with a certain amount of redundancy or excess capacity, but this is by no means unreasonable from an engineering point of view. Indeed, to design the pulmonary gas exchanger with a certain degree of redundancy may make a lot of sense. The lung forms the interface to the environment and its functional performance will thus depend on environmental conditions, such as the prevailing O_2 partial pressure, which falls as we go from sea level to higher altitudes. It has been shown that goats, whose DL_{O_2} is about twice as large as seemingly required, can maintain their maximal level of exercise-induced $\dot{V}_{O_2}$ even under hypoxic conditions whereas the dogs that have very small excess DL_{O_2} cannot. It has also been suggested that human athletes exercising at high altitude may fully exploit their DL_{O_2}. This suggests that the apparent redundancy in DL_{O_2} may be a safety factor to protect the good functioning of the pulmonary gas exchanger even when environmental conditions are not optimal. Recent studies with partial pneumonectomy in dogs have shown that the lung can achieve 85% of its maximal O_2 uptake even when 40% of lung tissue is removed after left pneumonectomy, making use of some of this reserve capacity; but when right pneumonectomy removes 60% of lung tissue, adequate function can be achieved only after compensatory growth of the residual lung tissue to restore diffusing capacity.[203–206]

■ Design of the Acinus and Gas Exchange

The preceding section considered the overall size of the gas exchanger of the entire lung to compare it with the global performance of this organ. In reality, the surface the size of a tennis court is subdivided into some 400 million gas-exchange units. These are individually perfused with blood because they correspond to the unit capillary network that spans between pulmonary arteriole and venule (Fig. 2-46). The diameter of such a roughly disk-shaped unit is about 500 μm and has a surface area that corresponds approximately to that of an alveolus, even though alveoli and the capillary unit are not congruent as the latter spans over several alveoli and each alveolus is in contact with several capillary units.[170]

These gas-exchange units are arranged along the terminal generations of the airway tree that form the pulmonary acinus (Fig. 2-61B). Note that this arrangement of gas-exchange units to the airway system differs from the common representation of the alveolar–capillary unit as a terminal "bubble" (Fig. 2-61A). This has potential functional consequences because ventilation of alveoli occurs in two steps:[207] (1) upon inspiration oxygen-rich air flows through the airways into the acinus carrying along O_2; (2) in the peripheral airways flow velocity slows down because the airway cross-section increases, and O_2 now moves toward the periphery by diffusion in the air phase, driven by the P_{O_2} gradient that becomes established as O_2 is absorbed at the alveolar surface (Fig. 2-62). Thus, in the peripheral airways diffusion along the airways is combined with diffusive permeation of O_2 into the alveoli and across the tissue barrier to the blood, the actual process of gas exchange. Whereas all capillary network units are individually perfused with venous blood the alveoli are not independent in terms of their O_2 supply, which depends on their location along the airway tree. Therefore, the design of the acinus has significant effects on the gas-exchange conditions.

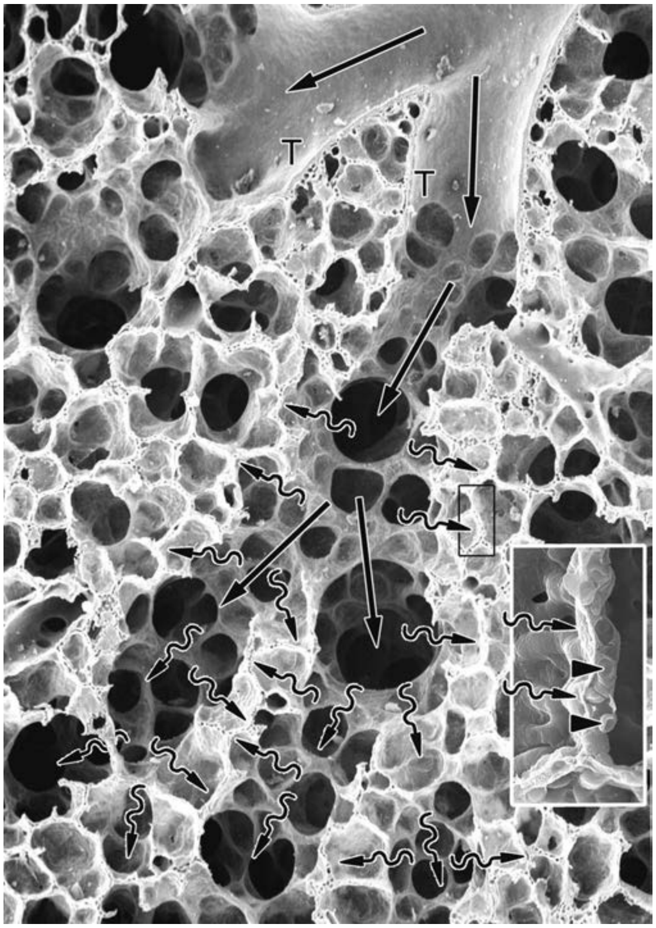

Figure 2-62 Central part of the acinar airways beginning with transitional bronchiole (T) and leading into the branched alveolar ducts. On inspiration air flows in by convection *(straight arrows)*, but as flow velocity falls diffusion of O_2 *(wiggly arrows)* becomes the dominant mechanism for bringing O_2 to the gas-exchange surface. All along acinar airways O_2 is absorbed by the capillary blood in the septa *(inset, arrowheads)*.

■ The Acinar Airway System Connected to the Gas Exchanger

In a systematic study of human lungs[9] the mean volume of acini was found to be 187 mm^3 with a standard deviation of 79 mm^3. The branching pattern for an average-size human acinus is shown in Fig. 2-63. The segment lengths have been drawn to scale, and

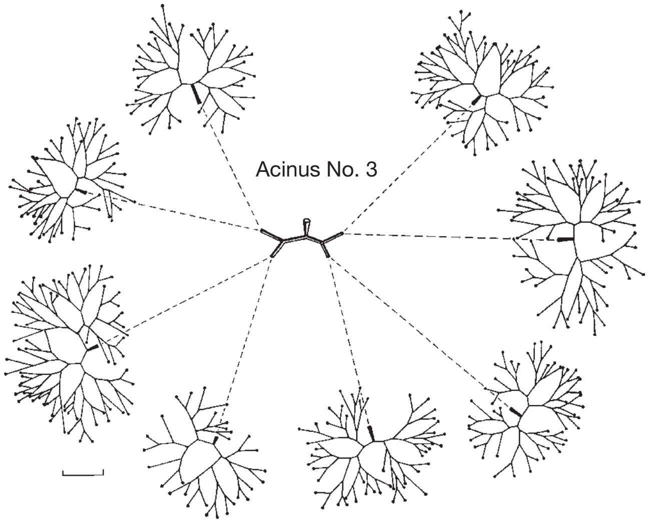

Figure 2-63 Graphic representation of branching pattern of acinar airways in one human acinus of 183 mm^3 volume with the segment lengths drawn to scale. The airways are separated at the third generation thus displaying the branching pattern within each 1/8 subacinus. *(Reproduced with permission from Haefeli-Bleuer B, Weibel ER: Morphometry of the human pulmonary acinus. Anat Rec. 1988;220(4):401–414.)*

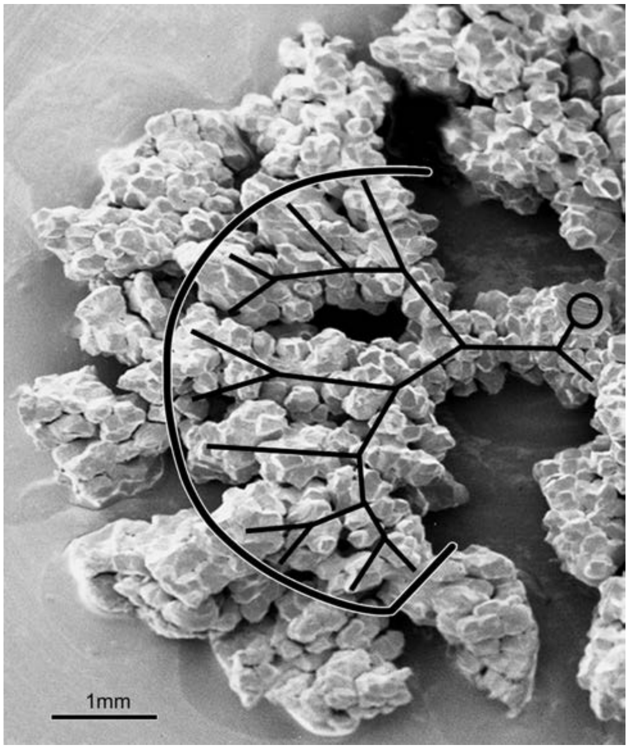

Figure 2-64 Airways of 1/8 subacinus of human lung beginning with generation 18 alveolar duct (circle). The silicon rubber cast has been spread out to show the course of the subsequent branchings. The curved line marks the approximate boundary to the last generation to show that this generation of alveolar sacs (see Fig. 2-5) comprises over half the gas-exchange area of the acinus.

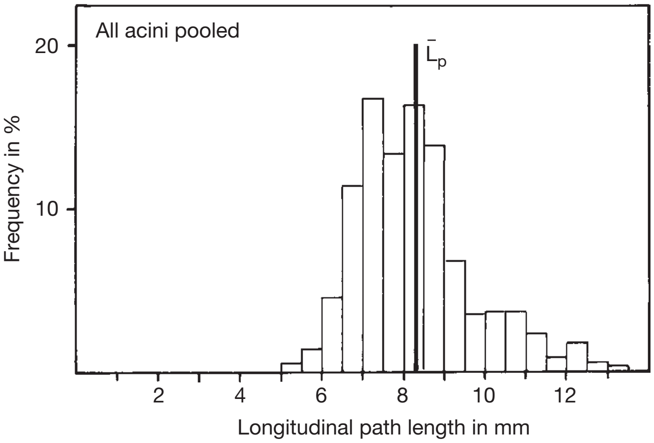

Figure 2-65 Frequency distribution of longitudinal path length from the transitional bronchiole to the alveolar sacs in the human lung. *(Reproduced with permission from Haefeli-Bleuer B, Weibel ER: Morphometry of the human pulmonary acinus. Anat Rec. 1988;220(4):401–414.)*

the terminal clusters of alveoli of the alveolar sacs are marked by a dot. This acinus has been subdivided into eight subacini whose substems are located in the third generation of acinar airways. The first three generations of acinar airways following on the transitional bronchiole are respiratory bronchioles, where there are only a few alveoli. In contrast, the alveolar ducts that follow are completely and densely lined with alveoli (Fig. 2-64). The 1/8 subacinus is a unit of functional significance, as we shall see. The intra-acinar airways branch by irregular dichotomy; terminal sacs are located in generations 6 to 11 so that the intra-acinar airways branch over an average of 8 generations (Fig. 2-5).

The morphometry of the intra-acinar airways of the human lung shows a number of characteristic traits. The inner diameter (d_{in}) that characterizes the cross-section of the duct tube decreases from about 490 μm at the transitional bronchiole to 270 μm in the last generations.[9] When this is plotted onto the graph relating airway diameter to generations of branching (Fig. 2-37), we note that this diameter falls less steeply than the cube-root-of-1/2 law we have observed for conducting airways. This is a significant finding in terms of the ventilation of alveoli by O_2 diffusion.

An important morphometric characteristic of acinar airways is the total path length for O_2 diffusion from the entrance at the transitional bronchiole to the terminal cluster of alveoli at the alveolar sac (Fig. 2-5). This path length is determined by two factors: the number of generations and the segment length. The length of alveolar ducts gradually decreases from 1330 to 640 μm in the peripheral generations, the alveolar sacs being a little bit longer. Since the number of branching generations varies somewhat, we can expect the path length to vary even within one acinus. In the human lung, the average longitudinal path length measures 8.3 ± 1.4 mm (Fig. 2-65).[10] Because of the decreasing length of acinar ducts 3.4 mm of this total path length are for the first three generations of respiratory bronchioles, whereas the path length of alveolar ducts and sacs comprised in the 1/8 subacinus (Fig. 2-64) averages 4.7 ± 0.88 mm.

Typical Path Model of Human Acinus

In view of assessing the effect of these structural features on the functional performance of the pulmonary gas exchanger we can attempt to develop what we may call a typical path model for an average human acinus[9,10]; the relevant morphometric data are given in Table 2-5. Such an acinus has a volume of 187 mm^3. Its airways branch over an average of eight generations to reach the terminal alveolar sacs. With each generation the number of branches doubles to end with some 256 terminal alveolar sacs in an average acinus (Fig. 2-63). Locating the transitional bronchiole ($z' = 0$) in generation 14 (Fig. 2-5) the terminal air sacs are in generation 23 of the typical path airway tree. From the estimates of the lengths and inner diameters of the airway segments we can derive

TABLE 2-5 Typical Path Model of Human Acinus

Generation		Segments			Dimensions per Generation			Path Length
Airways z	Acinus z′	N(z′)	l mm	d_{in} mm	$A_d(z')$ mm^2	$V_d(z')$ mm^3	$S_{alv}(z')$ mm^2	$L_p(z')$ mm
15	0	1	1.4	0.50	0.20	0.32	7	1.4
16	1	2	1.33	0.50	0.39	0.52	23	2.73
17	2	4	1.12	0.49	0.75	0.84	67	3.85
18	3	8	0.93	0.40	1.00	0.93	129	4.78
19	4	16	0.83	0.38	1.81	1.50	219	5.61
20	5	32	0.70	0.36	3.26	2.28	349	6.31
21	6	64	0.70	0.34	5.81	4.07	661	7.01
22	7	128	0.70	0.31	9.11	6.38	1204	7.71
23	8	256	0.70	0.29	16.9	13.47	2720	8.41

Modified with permission from Haefeli-Bleuer B, Weibel ER: Morphometry of the human pulmonary acinus. Anat Rec. 1988;220(4):401–414.

overall parameters of functional significance, such as the total airway cross-section per generation, $A_d(z')$, which is a determinant of air flow velocity (Fig. 2-44). Finally, we can also estimate the distribution of alveolar surface area to the different generations in proportion to the duct surface $S_d(z')$, adjusting for the fact that only part of this surface is associated with alveoli in the respiratory bronchioles (generations $z' = 1–3$). For an estimated alveolar surface of 130 m^2 in the human lung (Table 2-4), there would be about 54 cm^2 of gas-exchange surface per average acinus. It is seen that half this gas-exchange surface is in the last generation (see also Fig. 2-64). A final check of this model is that the path length from the entrance into the transitional bronchiole to the end of the alveolar sacs is 8.4 mm, which agrees well with the mean path length estimated in the human acini (Fig. 2-65).

Implications of Acinar Design for Gas-Exchange Function: The Phenomenon of Diffusion Screening

The gas exchange in the pulmonary acinus involves several physicochemical phenomena that occur within the complex acinar geometry described in the preceding section.[207] As mentioned, in the distal regions of the lung, oxygen is transported toward the alveolar membrane by both convection and molecular diffusion. Oxygen then diffuses through the tissue membrane into the blood, where it is bound by hemoglobin. Several physical parameters govern oxygen uptake at the acinar level, such as air flow velocity, diffusion coefficient of oxygen in air, alveolar membrane permeability, blood hemoglobin content, and its reaction rate with oxygen. Conversely, carbon dioxide is discharged from the blood to the alveolar gas through diffusion across the membrane. It then diffuses backward along the airways to the zone, where convection becomes dominant, and is lastly expelled from the lung. In all these processes, the morphology of the system plays an essential role.

Since oxygen uptake into the blood is driven by the O_2 partial pressure at the alveolar surface we must ask whether this driving force is the same throughout the acinus or whether there could be differences between its central and peripheral parts. Some earlier studies had shown that concentration gradients may exist as a consequence of efficient capture of oxygen by hemoglobin. More recently,[207] we have come to realize that such gradients are strongly influenced by the finite permeability of the membrane that plays a dominant role in the effective properties of the acinus as the ventilatory gas-exchange unit. O_2 molecules entering the unit where diffusion prevails have a larger probability to hit the surface of the alveolar membrane near the entrance than in the more distal regions. If the membrane permeability is large, O_2 molecules are absorbed at the very first hits. As a consequence, O_2 is absorbed into the blood in the first parts of the acinar pathway, a process called *diffusional screening,* so that the gas-exchange units in the deeper part of the acinus would receive less O_2 (Fig. 2-61) or perhaps even not enough for gas exchange to occur. Blood perfusing these regions would not be oxygenated and would thus appear as a shunt. In contrast, if the permeability is small, molecules will be absorbed only after many collisions with the wall. They then have a fair chance to reach the deeper regions and the entire acinar surface can be effective for gas exchange.

To put this into the perspective of structure–function relations this process is related to the balance between two conductances:[207] a diffusion conductance Y_{cross} for O_2 to *cross* the barrier from alveolar air to capillary blood, and a diffusion conductance Y_{reach} for O_2 to *reach* the surface through the airspaces. Both these conductances are determined by the product of (a) a physical parameter (the permeability coefficient for O_2 in tissue, and the diffusion coefficient for O_2 in air, respectively); and (b) a morphometric parameter (the gas-exchange surface, and the distance along the acinar airways, respectively). The physical coefficients are given quantities, except that the tissue permeability is also affected by the thickness of the tissue barrier, a parameter that varies very little between species. On the other hand, the size and surface of the acinus can be varied during evolution and growth to adjust the two conductances. We can predict that the design of the acinus is optimized if Y_{cross} and Y_{reach} are about equal, as this means that both the gas-exchange surface and the acinar air volume, or the diffusion distance, are matched. If Y_{cross} were much smaller than Y_{reach} the low permeability of the gas exchanger would need to be compensated by a larger gas-exchange surface, and this would inevitably entail a larger volume of the acinus to accommodate the surface and by that a longer diffusion distance.

The morphometric study of acini in various mammalian species[9,207,208] revealed that the size of the acini is such that $Y_{cross} \sim Y_{reach}$ so that their morphology seems to be at least partially adapted to minimize the effects of screening. Note that the problem of screening occurs in that part of the acinus where O_2 moves to the surface by diffusion only (Fig. 2-62), in what is called the *diffusion cell.* The transition between convection and diffusion is determined by the Peclet number (Fig. 2-66), essentially the ratio between air flow and diffusion velocities[207]; diffusion is more effective than convection when the Peclet number is smaller than 1. In the human lung, under resting conditions, this transition occurs in generation 18 and that is the entrance to the 1/8 subacinus (Fig. 2-63); accordingly, the diffusion cell corresponds to the 1/8 subacinus. In exercise, where O_2 consumption as well as ventilation is increased, convective transport

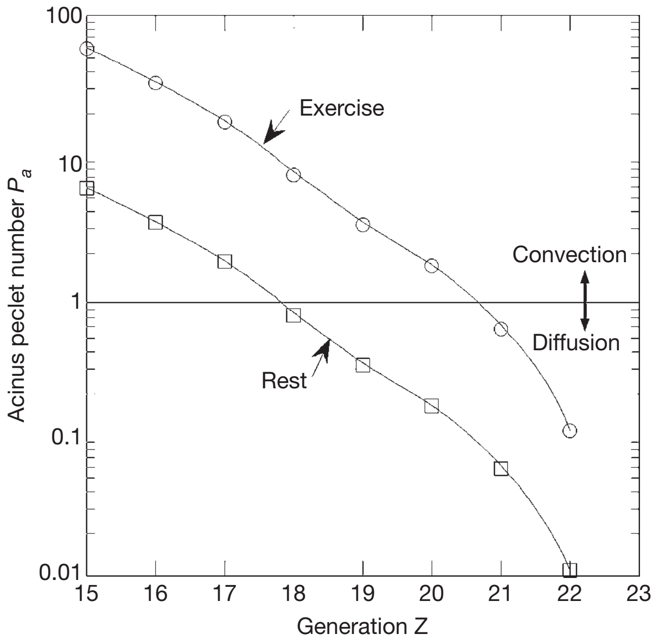

Figure 2-66 In the human acinus the Peclet number, reflecting the relation between convective flow velocity and diffusion velocity of O_2, falls as the airway cross-section increases. Below 1 diffusion becomes the dominant mechanism of alveolar ventilation. This transition point is about in generation 18 at rest and extends out to generation 21 in heavy exercise. *(Reproduced with permission from Sapoval B, Filoche M, Weibel ER. Smaller is better, but not too small: A physical scale for the design of the mammalian pulmonary acinus. Proc Natl Acad Sci USA. 2002;99(16):10411–10416.)*

of O_2 is effective out to generation 21 (Fig. 2-66). So in exercise there are only two to three generations of acinar airways that act as diffusion cell, but that is still highly significant because these generations accommodate 75% of the gas-exchange surface (Fig. 2-64 and Table 2-5).

Note that what has been discussed so far relates essentially to about half the respiratory cycle, namely, inspiration when fresh O_2-rich air is actively brought into the acinus. During expiration things are in a way reversed: CO_2 that has diffused from the blood into the acinar air now dilutes O_2 and the convection–diffusion front is moved toward the bronchi. For this reason, the effective duty cycle of the gas-exchange system is smaller than 1, particularly under the conditions of high O_2 uptake rate in exercise. This must be considered when modeling gas exchange. Recent refined model studies using the same morphometric data together with reasonable assumptions on the physiologic conditions revealed that the size of the human pulmonary acinus is such as to avoid negative effects of diffusional screening.[209]

The Lung as Part of the Pathway for Oxygen

The lung's main function, gas exchange between air and blood, serves the body's varying O_2 needs as they are set by the energetic demands of the cells and their mitochondria when these produce ATP by oxidative phosphorylation to allow the cells to do work. This process requires a flow of O_2 to be maintained from the lung to the cells[16] which proceeds along the respiratory system through various steps from the lung to the blood, by circulatory blood flow to the cells and mitochondria (Fig. 2-67). A number of basic features characterize this system: (1) under steady-state conditions the O_2 flow rate, $\dot{V}_{O_2}$, is the same at all levels; (2) the basic driving force for O_2 flow through the system is a cascade of O_2 partial pressures, which fall from inspired P_{O_2} down to near zero around the mitochondria; (3) the O_2 flow rate at each step is the product of an O_2 partial pressure difference and a conductance G, which is related to structural and functional properties of the organs participating in O_2 transfer. In the preceding section we have seen that the principal design features of the lung that determine one of the key conductances, the pulmonary diffusing capacity, are sized to just yield a conductance that allows the O_2 uptake required to satisfy the demands of the whole-body cell system at work, with a small margin of safety under normal conditions. Therefore, the lung appears designed to serve the body's needs efficiently and economically. The question we may now ask is whether the other parts of the respiratory system, from the heart to the mitochondria, also are designed for economic functional performance.[210]

Let us first look at the overall functional performance of the system. We first note that O_2 consumption is highly variable, increasing by about a factor of 10 between resting conditions and heavy exercise when 90% of the O_2 is consumed in the locomotor muscles. Figure 2-68 shows that the oxygen consumption in muscle is proportional to the energy output,[211] measured for example as running speed, and that it reaches a limit $\dot{V}_{O_2max}$ beyond which the running speed can still be increased, but the additional energy required by the higher speed is then supplied through glycolysis or anaerobic ATP production with the result that lactic acid concentration in the blood gradually increases. It is now interesting to note that $\dot{V}_{O_2max}$ is a characteristic of the work capacity of an individual: well-trained athletes reach their $\dot{V}_{O_2max}$ at a higher running speed and a higher level of oxygen consumption, and lactic acid concentration in the blood also begins to increase at the higher performance levels corresponding to $\dot{V}_{O_2max}$ (Fig. 2-68).

One may now raise the question whether this variable limitation of oxidative metabolism is a result of variable functional constraints affecting the regulation of metabolic rate and circulatory transport, or whether it could be set by variations in design constraints characterizing the structural components of the pathway, one possible candidate being the pulmonary diffusing capacity. The answer to this question depends on an integrated study of structure and function of the respiratory system. For this we need a quantitative model of the oxygen pathway that identifies all the functional variables and the design parameters at the four levels of the system[212]: the lung,

$\dot{V}_{O_2}(B) = (P_a - P_v)_{O_2} \times G(B)$
$\dot{V}_{O_2}(B\text{-}C) = (P_b - P_c)_{O_2} \times G(B\text{-}C)$
$\dot{V}_{O_2}(C) = (P_c - ?)_{O_2} \times G(C)$

Figure 2-67 Model of the respiratory system from the lung to the cells. Oxygen flow is driven through the system by a cascade of P_{O_2} ranging from inspired to near zero at the mitochondria. At each level the flow rate is determined by a partial pressure difference and a conductance. *(Modified with permission from Taylor CR, Weibel ER: Design of the mammalian respiratory system. I. Problem and strategy, Respir Physiol. 1981;44(1):1–10.)*

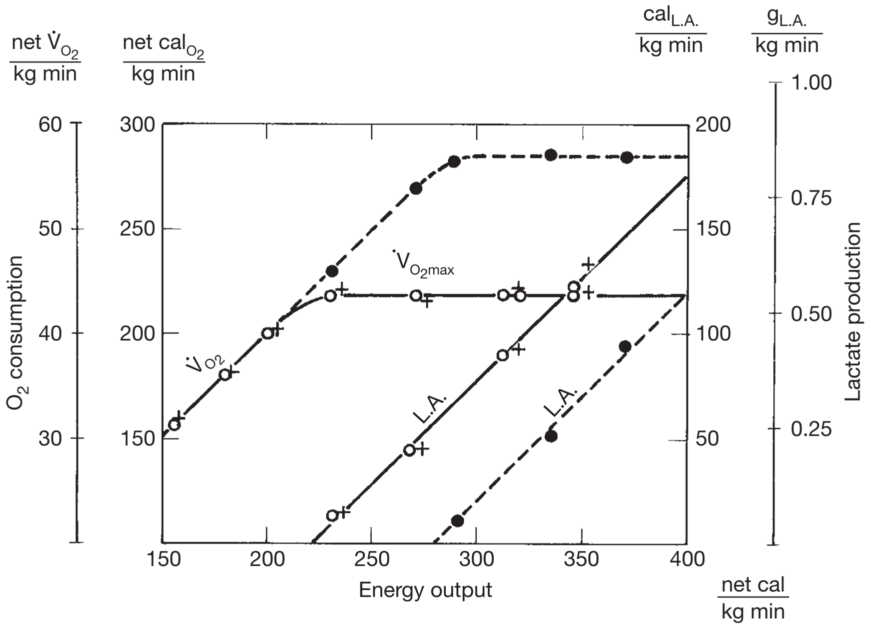

Figure 2-68 Rate of O_2 consumption *(left ordinate)* and lactic acid production *(ordinate at right)* in exercise are plotted as a function of the work intensity and, therefore, of the energy requirement *(abscissa)*. Oxygen consumption increases linearly up to a point corresponding to an energy requirement of 220 cal/kg min^{-1}; if work is pushed beyond that there is no further increase in O_2 consumption ($\dot{V}_{O_2max}$ is reached) but glycolysis now generates the required energy resulting in an increase in lactic acid production. The broken lines refer to athletes (middle- and long-distance runners) whose maximum oxygen consumption is higher; the line of the lactic acid for these subjects is correspondingly shifted to the right. *(Reproduced with permission from Margaria R, Cerretelli P, Diprampero PE, et al. Kinetics and mechanism of oxygen debt contraction in man. J Appl Physiol. 1963;18:371–377.)*

circulation of blood with the heart, capillaries, and mitochondria (Table 2-6). This model is a further development of the one shown in Fig. 2-67 in the sense that, at each level, the equation describing oxygen flow rate sorts out the parameters of functional regulation and those of structural design. These are distinguished in the following sense: Functional variables are regulated according to need with short time constants (seconds), whereas structural design parameters are genetically determined static elements that can be adjusted to a certain extent, for example, by training, but with time constants of weeks to months.

Thus, design variables set the capacity of the system because they are determined by structures whose quantitative properties cannot be adjusted at short notice. If the system were designed according to the principle of symmorphosis we would predict that the design variables are adjusted to $\dot{V}_{O_2max}$ at all levels from the lung to the mitochondria.

The experimental test of this hypothesis requires the integrated measurement of $\dot{V}_{O_2max}$ of the relevant functional parameters, and of all the design parameters, which must then be correlated on the basis of the model of Table 2-6. This cannot be easily done in the human, so that is where we can learn from studies in comparative physiology. We know that $\dot{V}_{O_2max}$ is highly variable among mammals. Some species such as dogs, horses, or pronghorn antelopes have a much higher level of $\dot{V}_{O_2max}$ than "normal" species of the same size such as goats or cows; this is called *adaptive variation*.[213] On the other hand body size matters so that small animals have a higher metabolic rate per unit body mass than large species, which is called *allometric variation*.[210] These are genetically determined variations, the result of evolution and selection by fitness, in contrast to the changes in overall work capacity and $\dot{V}_{O_2max}$ induced by exercise training in human athletes, which are epigenetic variations.[214,215] In all these cases we can ask how and to what extent the structural design parameters are adjusted to meet the different requirements for O_2 to cover the energetic need at the limit of the aerobic work capacity. If there is a bottleneck, then there will be one and only one parameter whose variation is perfectly matched to the variation in the limit of O_2 flow, $\dot{V}_{O_2max}$, whereas all the parameters that are overdesigned would appear in haphazard relations to the flow limit. On the other hand, if the limiting resistances are distributed all steps would have to be matched to the varying $\dot{V}_{O_2max}$. If we take the bold view that the organisms are economically designed we would predict that the structural parameters at all levels should be sized to the maximal total O_2 flow requirement with no unnecessary excess capacity because that would be a waste. We have called this design principle *symmorphosis*, meaning that there should be no more structure built into the system than required to serve the functional needs.[189]

TABLE 2-6 Model of Structure–Function Relations in Pathway for Oxygen Separating Functional and Structural Parameters in the Equations Defining O_2 Flow Rate Through Four Levels

FUNCTION • DESIGN
$\dot{V}_{O_2}$ (lung) = $(P_{A_{O_2}} - Pb_{O_2})\{t_c, \theta_{O_2}\} \bullet D_{L_{O_2}}\{S(A), S(c), V(c), \tau_{hb}\}$ (1)
$\dot{V}_{O_2}$ (heart) = $(\sigma_a \cdot Pa_{O_2} - \sigma_{\bar{v}} \cdot P\bar{v}_{O_2}) \cdot f_H \bullet Vs\{V(LV)\} \ldots V_v\,(ec)$ (2)
$\dot{V}_{O_2}$ (caps) = $(Pb_{O_2} - Pc_{O_2})\{tc\theta_{O_2}\} \bullet D_{T_{O_2}}\{S(c), V(c), V_v\,(ec), \delta(c,mi)\}$ (3)
$\dot{V}_{O_2}$ (mito) = $\dot{V}_{O_2}\{\dot{m}_{ATP}\} \bullet V(mi)\{S_V\,(im,mi)\}$ (4)

The O_2 flow rate $\dot{V}_{o_2}$ is expressed as the product of functional and design parameters; parameters that affect the factors are shown in italics and placed in braces {.}. The functional parameters include: O_2 partial pressures (P_{O_2})*, coefficients of "hematocrit-specific" O_2 capacitance (σ) which depend on O_2-hemoglobin dissociation, O_2 binding rate* (θ)*, heart frequency (f_H), capillary transit time* (tc)*, and mitochondrial O_2 consumption rate as function of ATP flux* ($\dot{V}_{o_2}\{\dot{m}_{ATP}\}$)*. Design parameters include: diffusion conductances* (D) *of lung and tissue gas exchangers which depend on alveolar and capillary exchange surface areas* (S(*A*), S(c))*, capillary volumes* (V(c))*, hematocrit* (V_V(ec))*, harmonic mean barrier thickness* (τ_{hb})*, capillary-mitochondrial diffusion distance* (δ(c,mi))*, and mitochondrial volume* (V(mi)) *with inner membrane surface density* (S_V(im,mi)).
Data from Weibel ER: Symmorphosis: on form and function in shaping life. Cambridge, MA: Harvard University Press; 2000.

Testing the Hypothesis of Symmorphosis

To test such a hypothesis, we can first compare mammals that greatly differ in terms of their maximal O_2 consumption. The first type of this variation is found in comparing normal with athletic species, such as dogs with goats or horses with steers.[213] It has been found that such athletic animals can achieve a $\dot{V}_{O_2max}$ that is about 2.5 times higher than that of normal species of the same size. This is much more than

what human athletes can achieve. The relevant morphometric data on such species are shown in Table 2-7 for three species pairs.[216] If we go through the respiratory system, beginning at the bottom with the mitochondria, we note that their total volume in the locomotor muscles is also 2.5 times greater in the athletic species with the result that, at $\dot{V}_{O_2max}$ the unit volume of mitochondria consumes the same amount of oxygen in all these six species, namely about 5 mL O_2 per minute and mL mitochondria. In the next level up, the muscle capillaries, we note that the capillary volume is only 1.7 times greater in the athletic species. However we note that in the athletes the hematocrit, that is, the concentration of erythrocytes in the blood, is larger so that as a result the capillary erythrocyte volume, the product of capillary volume with hematocrit, is 2.44 times greater, thus well matched to the mitochondrial O_2 demands. Note that this is what counts because oxygen is delivered exclusively from the capillary red blood cells. When we look at the determinants of total blood flow the heart is the central element. We notice that athletic species have larger hearts resulting in a larger stroke volume Vs, but that the maximal heart frequency is not different between the species pairs so that cardiac output is determined by the stroke volume. This is only 1.7 times greater in the athletic species. However, note that, here again, the hematocrit plays an important role as it determines the amount of O_2 that can be transported to the capillaries. If we calculate the cardiac erythrocyte output $\dot{Q}$ (ec) we find that it is again 2.4 times greater in the athletic species. Thus, the design parameters of the internal steps of the O_2 transport cascade are quantitatively adjusted to the needs for O_2 flow under limiting conditions. Thus, it appears that the resistance to O_2 flow is distributed to all levels.

When we then consider the design of the pulmonary gas exchanger, we note that the O_2 diffusing capacity of the lung of athletic species is only 1.7 times greater than that of normal species. Considering that we found that the human lung may have some excess capacity by about a factor of 1.5, this may signify that normal sedentary species such as goats or cows have a greater excess capacity than athletic species. Indeed, this can be shown to be the case in two ways:[217] (1) when one calculates the progression of O_2 loading on capillary blood (Bohr integration, Fig. 2-59) one finds that dogs reach saturation just before the blood leaves the capillaries into arterial blood, whereas the goats have some 30% reserve capacity; (2) when goats are run on a treadmill while breathing hypoxic air one finds that they can maintain their $\dot{V}_{O_2max}$ in contrast, dogs cannot run at their established $\dot{V}_{O_2max}$ under such conditions. We concluded from this observation that athletic species have designed a lung to match the requirements for maximal O_2 uptake with no excess capacity while normal sedentary species apparently allow for a certain safety margin that allows them to perform well also under unfavorable hypoxic conditions. If this is now applied to our observations on the human lung this may mean that the excess capacity of the normal lung may just be sufficient to allow athletes to increase their $\dot{V}_{O_2max}$ by training by a factor 1.5, just about what they can achieve (Fig. 2-67).

One has also found that highly trained athletes do not tolerate heavy exercise at very high altitudes as they cannot achieve O_2 saturation of their arterial blood. Thus, it seems that the pulmonary gas exchanger is now the limiting factor for O_2 transfer to the working muscles. The reason for this is that the lung of the adult cannot enlarge its gas-exchange surfaces to match the increased demands of trained muscles. So an athlete must make do with the lung she or he has developed during growth. This contrasts with the changes induced by exercise training in muscle with an increase in mitochondria and capillaries, and in the heart by enlargement of the ventricles, all well matched to the maximal O_2 demands.[212] Therefore, it is fortunate—and perhaps a sign of good design—that the lung is designed with some excess diffusing capacity to allow the lower, internal, levels of the respiratory system to exploit their capacity to adapt to increased energetic needs.

CHAPTER 3

The Respiratory Muscles

Ghislaine Gayan-Ramirez
Daniel Langer
Marc Decramer

INTRODUCTION

The respiratory muscles constitute a complex pump system. Several muscles constitute this system, represented schematically in Figure 3-1. Breathing under all circumstances requires a coordinated contraction of different respiratory muscles. The most important inspiratory muscle is the diaphragm. The conditions under which this respiratory muscle system weakens and eventually will fail are addressed in other chapters. This chapter focuses on structural and functional properties of the respiratory muscles, respiratory muscle action, and respiratory muscle interaction.

STRUCTURAL AND FUNCTIONAL PROPERTIES OF RESPIRATORY MUSCLES

The respiratory muscles are skeletal muscles, and, in essence, their structural and functional properties are within the range of other skeletal muscles located in the limbs. Adaptations to their specific function, however, make them distinctly different from other skeletal muscles in a number of respects. First, limb muscles are essentially designed to produce movements, and hence, primarily work against inertial loads. Respiratory muscles mainly have to overcome resistive and elastic loads.

Second, peripheral muscles contract rhythmically during movements, whereas respiratory muscles contract rhythmically and continuously, and they are the only skeletal muscles on which life depends. These vital muscles thus have to be well equipped to sustain continuous rhythmic contraction. These adaptations include high fatigue resistance, high oxidative capacity, greater capillary density, and greater maximal blood flow, and they depend upon structural and functional properties of the muscles.

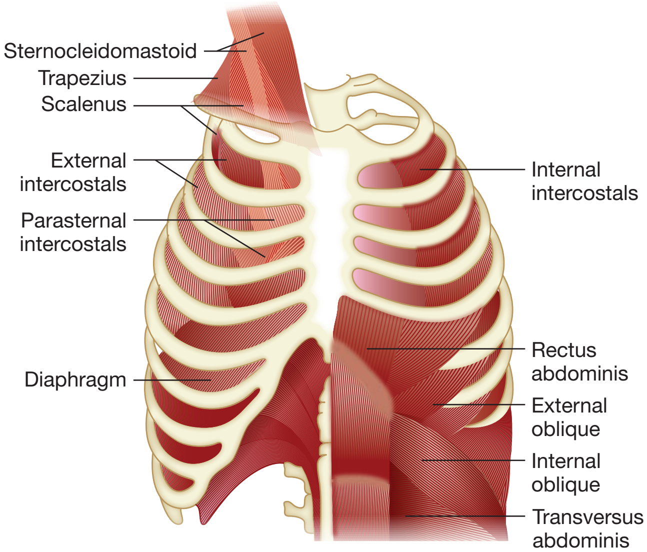

Figure 3-1 Idealized drawing of the respiratory muscles.

Structural Properties

Structural properties of muscles in general, and respiratory muscles in particular, depend upon fiber types present in the muscle, morphologic characteristics of the fibers, and motor unit organization.

Fiber Types

Four types of muscle fibers are usually present in skeletal muscles. They are distinguished on the basis of the myofibrillar myosin adenosine triphosphatase (ATPase) activity and its pH dependence and pretreatment with paraformaldehyde.[1,2] Thus, after acid preincubations at pH 4.5, type I fibers are stained dark, and type IIa fibers are stained lighter than type IIb and type IIx fibers. In addition, pretreatment with paraformaldehyde after alkaline preincubation at pH 10.4 further allows the distinction between type IIb fibers staining lighter than type IIx fibers. Alternatively, muscle fibers may be distinguished through myosin heavy chain gene expression using electrophoresis and western blotting or via immunostaining.[3] This latter technique has the advantage of revealing the presence of coexpression of different myosin heavy chain isoforms within the same muscle fiber. It has also been revealed that myosin heavy chain 2b is not expressed in human muscle.[4] Type I fibers, or slow oxidative fibers, have a slow contraction profile but are high in endurance and rich in oxidative enzymes.[5] Type II fibers are fast-twitch fibers that develop tension rapidly. They either are fatigue resistant or glycolytic oxidative (IIa), or fatigable or glycolytic (IIb),[5] whereas resistance to fatigue for the type IIx fibers is intermediate between the IIa and IIb fibers. Type II fibers develop greater forces than do type I fibers. Muscles primarily composed of type I fibers have high endurance capacity, whereas those primarily composed of type IIb fibers are designed to develop high forces but have low endurance capacity.[5] Type IIa fibers are intermediate and combine relatively high force development with relatively long endurance.[5] In general, type I fibers have the smallest cross-sectional area, and type IIb fibers tend to have the largest.

The respiratory muscles are mixed muscles containing both fast-twitch and slow-twitch fibers. The human diaphragm contains about 55 ± 5% type I fibers, 21 ± 6% type IIa fibers, and 23 ± 3% type IIx fibers. Other respiratory muscles (i.e., intercostal muscles, abdominal muscles, sternomastoids, scalenes) contain at least 60% highly oxidative fibers.[6,7] The respiratory muscles thus are generally well equipped to sustain continuous rhythmic contraction.

Morphologic Characteristics of the Fibers

The respiratory muscles consist of muscle bundles oriented in a parallel fashion. These bundles consist of hundreds of muscle fibers, each of which in turn consists of hundreds of myofibrils. These myofibrils are made up of hundreds of sarcomeres arranged in series, each sarcomere consisting of a number of myosin (thick filaments) and twice the number of actin (thin) filaments. The capacity of the muscle to produce forces depends upon the number of myofibrils in parallel, since the forces developed by all these myofibrils are additive, whereas the displacement and velocity of shortening depend upon the number of sarcomeres in series. Indeed, the displacements of these sarcomeres arranged in series are additive.

The density of mitochondria in each of the four fiber types tends to be greater than in the same fiber types in limb muscles.[5,8] In addition, in humans, the diaphragm is composed of about 80% oxidative fibers compared with 36% to 46% in the limb muscles of untrained men.[5,8] As a consequence, the volume density of mitochondria in the diaphragm is twofold greater than in the limb muscles.[5,8] Therefore, the oxygen uptake capacity of the diaphragm is considerably greater than that of limb muscles because of the high oxidative fiber content and the greater mitochondrial density.[5,8] Moreover, the maximal blood flow also considerably exceeds that of limb muscles because of the greater capillary density, which is about twice the capillary density in the limb muscle. The diaphragm is thus well equipped to sustain rhythmic contraction at rest through its type I and IIa fibers: The type IIa fibers permit additional recruitment in power and rate during exercise, and the few type IIx fibers permit high power outputs necessary for sneezing and coughing.

Motor Unit Organization

Muscle fibers are organized by their innervations in motor units that vary in their mechanical and fatigue properties. In adults, all muscle fibers within a motor unit are the same fiber type. The muscle fibers within a given motor unit are broadly dispersed throughout a region of the diaphragm. Dispersion occurs both horizontally across the surface of the diaphragm and vertically with fibers at different depths. The innervation ratio (number of fibers supplied by a single motoneuron) is approximately 400 in rat diaphragm[9] compared with an estimated value of 2500 in humans.[10] There are four types of motor units in the respiratory muscles: a motor unit with slower contraction times and resistance to fatigue (type S) and three types of motor units displaying faster contraction times, with various degrees of fatigue resistance. The type S comprises fibers that express the slow isoform of myosin heavy chain. Fast motor units that are fatigue resistant (type FR) comprise muscle fibers expressing the myosin heavy chain 2a; those that are highly fatigable (type FF) comprise muscle fibers expressing myosin heavy chain 2b; and those that are fatigue intermediate (type FInt) comprise muscle fibers that express the myosin heavy chain 2x. Motor units composed of fast fibers are large and develop forces in the range of 110 millinewtons (mN). These, however, are considerably smaller than in limb muscles. Motor units composed of slow fibers are smaller and develop forces in the range of 30 to 60 mN. The recruitment pattern of the diaphragm follows the size principle with the smallest motor units being recruited first.

■ Functional Properties

There are different ways to assess functional properties of respiratory muscles. Respiratory muscle strength is usually assessed by maximal static pressures measured at the mouth.[11] Validated reference values are available. Respiratory muscle strength can also be evaluated by determining esophageal, gastric, and transdiaphragmatic maximal pressures, although there is a lack of widely accepted reference equations.[11] Non-volitional maneuvers, obtained through electrical or magnetic stimulation, can be employed in patients unable to cooperate.[11] Muscle endurance also can be assessed, generally using repeated submaximal maneuvers until exhaustion, but no validated reference values are available yet.[11] Evaluation of contractile properties of respiratory muscle using ultrasound imaging also has gained popularity as a clinical tool in recent years.[11] There are also several techniques available to evaluate respiratory muscle neurophysiology, but mainly for research purposes. Applications and technical specifications of these techniques include (1) electromyography (EMG) to measure the output of the respiratory motor neurons, (2) electroencephalography (EEG), which tests the involvement of motor and premotor areas, and (3) transcranial magnetic stimulation (TMS), which assesses the neural pathways to the respiratory muscles (described in more details elsewhere).[12] Finally, near infrared spectroscopy has recently gained popularity as a technique to evaluate local respiratory muscle perfusion and metabolism.[13]

Functional properties of muscles are generally described in terms of force–length relationships, time-dependent characteristics of the twitch, force–frequency, force–velocity, and power–frequency relationships.

The force–length characteristics of the diaphragm are, in essence, similar to other muscles. Maximal tension is generated at the optimal length. Three aspects of the force–length curve of the diaphragm are potentially relevant to clinical medicine. First, with hyperinflation, the diaphragm shortens and its capacity to generate force is concomitantly reduced.[14] Second, when hyperinflation occurs chronically, adaptation occurs in the muscle. This adaptation consists of dropout of sarcomeres such that muscle shortening is then accommodated by a reduced number of sarcomeres rather than alterations in filament overlap within the sarcomeres.[15] As a consequence, the force-generating capacity is restored, at least in part, at foreshortened length.[15] This adaptation is summarized in Figure 3-2. The consequences of this adaptation to patients with hyperinflation are discussed in the section "Physiologic Conditions Affecting Respiratory Muscle Interaction." Third, although less-than-optimal filament overlap is the primary reason for a reduction in force with muscle shortening, calcium deactivation due to T-tubular failure also plays a role.[16] This is potentially significant for treatment, since inotropic agents restore T-tubular function in foreshortened muscle.[17] Accordingly, inotropic agents exert much greater effects on foreshortened diaphragm than on diaphragm placed at its optimal length.[18] This concept opens up new perspectives for respiratory muscle pharmacotherapy in patients with severe hyperinflation. The length–tension curves of other respiratory muscles and their adaptation to hyperinflation have not been systematically studied.

A particularly interesting question is the relationship between the in situ operational length of the respiratory muscles and the optimal length in vitro. For the diaphragm, the length at functional residual

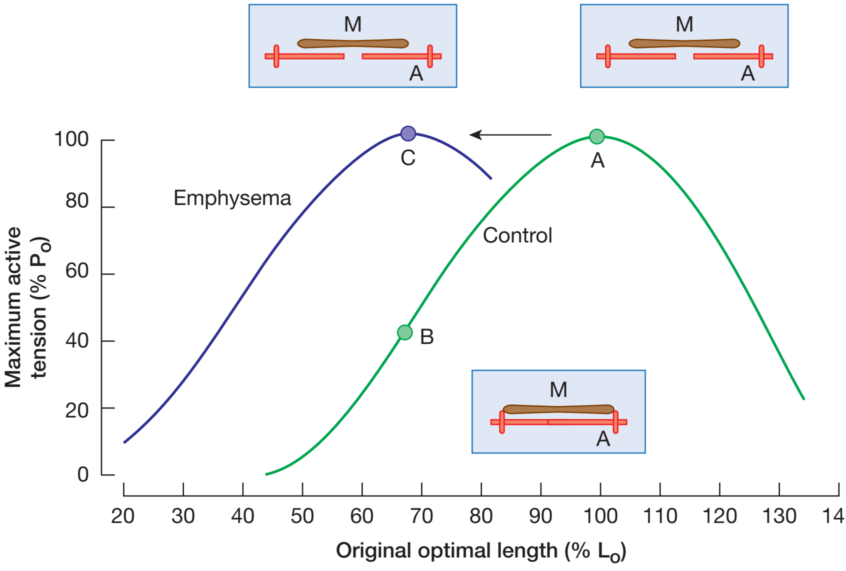

Figure 3-2 Diaphragmatic length–tension curve in normal hamsters and hamsters with elastase-induced emphysema. Tension is expressed as a percentage of maximum tetanic tension, P_o, and length is expressed as a percentage of original optimal length, L_o. The degree of filament overlap among actin (A) and myosin (M) filaments in control (**A**), acute (**B**), and chronic hyperinflation (**C**) is shown. Note that due to sarcomere adaptation in chronic hyperinflation, the degree of filament overlap is the same at a considerably shorter length. *(Reproduced with permission from Farkas G: Functional characteristics of the respiratory muscles. Sem Respir Crit Care Med. 1991;12(4):247–257.)*

capacity (FRC) comes close to the optimal length.[19,20] The length changes undergone by the diaphragm over the vital capacity range are large, 30% to 40%.[21,22] These length changes are considerably smaller for the parasternal intercostals, the scalenes, and the sternocleidomastoids.[23–25] For the parasternal intercostals, the length at FRC is clearly longer than optimal in supine dogs, so that with hyperinflation, the parasternal intercostals move toward their optimal length.[25,26] Subsequent experiments, however, indicate that the fall in pleural pressure caused by stimulation of the parasternal intercostals in dogs is reduced with increasing lung volume.[27] This discrepancy was shown to result from changes in orientation and motion of ribs with hyperinflation. The scalenes and sternocleidomastoids appear to operate on the ascending limb of their length–tension curves in supine dogs.[24] How hyperinflation in patients affects the force-generating capacity of these muscles remains unclear. According to an analysis, the changes in length during passive inflation are proportional to the mechanical advantage of a particular respiratory muscle.[28] In keeping with this analysis, the mechanical advantage of the diaphragm would be considerably greater than the mechanical advantage of other inspiratory muscles (see in the section "Physiologic Conditions Affecting Respiratory Muscle Interaction").

The force developed by a muscle increases with increasing frequency of stimulation. The increase in force is considerably steeper for a slow muscle in which fusion occurs at lower frequency because of the longer relaxation time than for a fast muscle. The diaphragm is intermediate, so that at in vivo stimulation frequencies (10–30 Hz), a fused tetanic contraction occurs. Particularly interesting is the effect of acute shortening on the force–frequency curve. Since acute shortening is associated with a downward shift of the force–frequency curve, the detrimental effect of acute shortening on the force-generating capacity of the diaphragm appears to be twofold.[14] With muscle shortening there is a clear reduction in maximal tetanic force. However, the decrease in force at submaximal stimulation frequencies is disproportionately greater (Fig. 3-3).

The force–velocity curve of the diaphragm is shown in Figure 3-4. With increasing loads, the velocity of contraction is reduced. The velocity of contraction is a direct function of myosin ATPase activity, and, hence, the force–velocity curve is primarily determined by the muscle fiber composition. The diaphragm is intermediate between the force–velocity curve of a fast and a slow muscle (Fig. 3-4).[6] The production of airflow into the lungs requires power output by the respiratory muscles. Power may be calculated as the product of the values of velocity and force according to the force–velocity relationship (Fig. 3-4). Instantaneous peak power occurs at 30% of maximal force and at 30% of maximal velocity. The frequency–isometric force relationship, frequency–shortening force, and frequency–power relationships show a similar dependency of force and power upon frequency of stimulation.

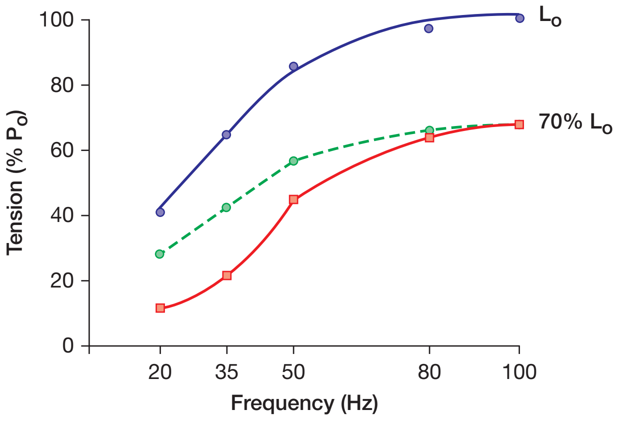

Figure 3-3 Force–frequency curve of human diaphragm at optimal length (L_O) and 70% L_O. Force is expressed as a percentage of maximal tetanic tension, P_O, and frequency is expressed in Hz. *Dashed line* is the predicted line at 70% L_O, whereas the *solid line* is the observed line. The predicted line is based on the assumption that a 30% change in length produces a 35% drop in force at all stimulation frequencies, as is observed for maximal tetanic force. Note that the decrease in force at lower stimulation frequencies is considerably greater than theoretically predicted. *(Reproduced with permission from Farkas G: Functional characteristics of the respiratory muscles. Sem Respir Crit Care Med. 1991;12(4):247–257.)*

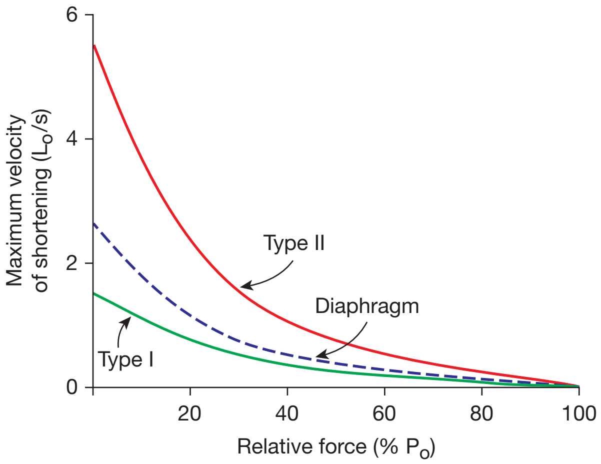

Figure 3-4 Force–velocity curve of human diaphragm *(dashed line)*, which is intermediate between the force–velocity curve of a typical slow muscle (type I) and a typical fast muscle (type II). Maximum velocity is expressed in optimal length (L_O), per second and relative force is expressed as a percentage of maximum tetanic force, P_O.

Fatigue also affects profoundly the force–length, force–frequency, force–velocity, and power–frequency characteristics of the diaphragm. The diaphragm, however, is more resistant to developing fatigue than limb muscles in vivo and in vitro.[29] Of note, the inspiratory muscles recover from fatigue 10 times faster than the elbow flexors performing a similar task.[30] The effects of fatigue on functional properties of the respiratory muscles are discussed in Chapters 84 and 103. The factors determining the development of respiratory muscle fatigue also are discussed in these chapters.

ACTIONS OF RESPIRATORY MUSCLES

Below we consider the actions of individual respiratory muscles or groups of muscles, beginning with the diaphragm.

The Diaphragm

The diaphragm is the most important inspiratory muscle. It is innervated by the phrenic nerves supplied by the cervical nerve roots C3 to C5 in humans. It consists of two distinct parts, the costal and crural parts, which have separate actions on the rib cage, separate segmental motor innervations, and a different embryologic origin. In respiratory activities, however, the diaphragm frequently operates as a functional unit, and in the following its action is described as such. Diaphragmatic action is schematically represented in Figure 3-5. Diaphragmatic contraction increases chest wall dimensions because of three distinct reasons. First, diaphragmatic descent increases the craniocaudal dimensions of the thorax. Diaphragmatic descent is tightly coupled to outward motion of the free abdominal wall.

Second, diaphragmatic contraction increases the dimensions of the lower rib cage because of the increase in abdominal pressure that it causes. This increase in abdominal pressure acts through the zone of apposition (i.e., the zone in which the diaphragm is immediately apposed to the rib cage) to expand the lower rib cage. This action is

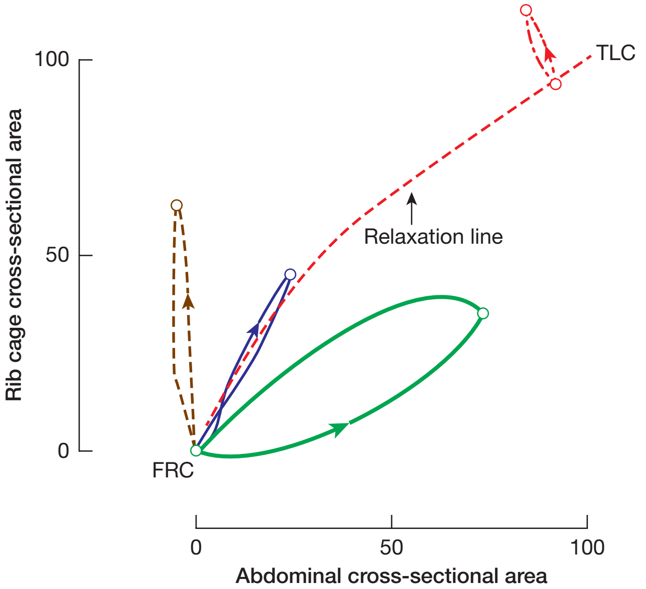

Figure 3-6 Konno–Mead diagram illustrating chest wall motion during quiet breathing *(thin loop)*, diaphragmatic pacing or quiet breathing in tetraplegic patient *(thick loop)*, breathing with diaphragm paralysis *(dash loop)*, and breathing at severely elevated end-expiratory volume *(dash–dot loop)*. Rib cage and abdominal cross-sectional areas are expressed as a percentage of inspiratory capacity. *Dashed line* is the relaxation line obtained during expiration with muscles relaxed.

the appositional component of diaphragmatic action (Fig. 3-5).[31,32] The magnitude of the appositional component is determined by the magnitude of the zone of apposition, about 25% to 30% of the total internal surface area of the rib cage at FRC in standing humans, and by the magnitude of the increase in abdominal pressure caused by diaphragmatic contraction.[32]

Third, diaphragmatic contraction further increases lower rib cage dimensions because of its insertions into the lower rib cage. The diaphragmatic fibers are oriented axially, and their contraction causes pull on the lower rib cage in an axial direction, leading to cephalad motion and outward rotation of the lower rib and hence, to lower rib cage expansion. This is the *insertional component* of diaphragmatic contraction (Fig. 3-5).[31]

When the diaphragm acts in isolation during diaphragmatic contraction or pacing in high quadriplegics, in whom all inspiratory muscles, except for sternocleidomastoids, are paralyzed,[33,34] it exerts an expiratory effect on the upper rib cage during inspiration.[33,35] These data point out that in normal subjects, quiet inspiration is not accomplished by the diaphragm alone but rather results from the coordinated activity of the diaphragm with the rib cage inspiratory muscles and the abdominal muscles. Indeed, the pattern of chest wall motion in quadriplegics shown in Figure 3-6 indicates that diaphragmatic contraction alone cannot be responsible for the pattern of chest wall motion observed during quiet breathing (see in the section "Physiologic Conditions Affecting Respiratory Muscle Interaction") and hence, that other muscles assist the diaphragm in moving the chest wall during quiet breathing.

The Intercostal Muscles

The functional anatomy of intercostal muscles is schematically represented in Figure 3-7. Between the chondral portions of the ribs only one layer of intercostal muscles, the parasternal intercostals, is present. Between the osseous portions of the ribs, two layers are present. The outermost layer runs obliquely downward and forward and is called the *external intercostal*. The innermost layer runs obliquely downward and backward and is called the *internal intercostal* (Fig. 3-7, left panel). Note that the internal intercostals and parasternal intercostals have the same fiber orientation. Dorsally only an external intercostal is present. Finally, the fusiform muscle running from the lateral border of the transverse processes of the thoracic vertebra and inserting caudally into the rostral border of the rib below is called the *levator costae* (Fig. 3-7, right panel).

The parasternal portion of the intercostal musculature, the "parasternals," is consistently active during quiet breathing both in animal and human subjects,[23,36] and is the most important inspiratory portion of the intercostal musculature. The parasternal intercostals have the greatest mechanical advantage, and their contraction produces about 60% of the cephalad motion of the rib during inspiration.[37,38]

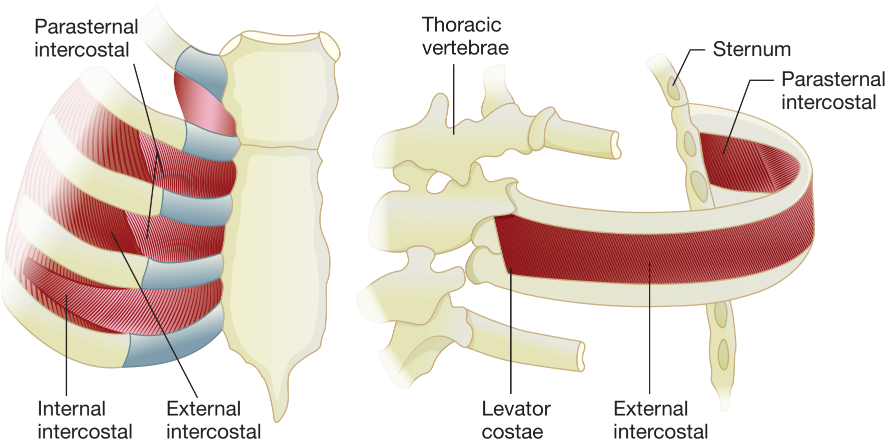

Figure 3-7 Diagram of the functional anatomy of the intercostal muscles, at their anterior *(left)* and posterior *(right)* aspects. Notice the parasternal, internal, and external intercostals, and the levator costae.

Within the parasternal intercostals, the medial fibers have a greater mechanical advantage and are activated more consistently and before the middle and lateral fibers.[39]

The action as well as the respiratory role of the interosseous intercostals remain the subject of a longstanding debate. The most commonly accepted view on intercostal muscle action is based on a theory of intercostal muscle fiber orientation and rib geometry. This theory states that the external intercostals are inspiratory in action, and the internal intercostals are expiratory in action.[40] Numerous experiments do not fit with this theory, although a finite element analysis largely confirmed these actions.[40] It is commonly believed that the interosseous intercostals constitute a reserve system that may be recruited with increased ventilatory load. The external intercostals are recruited predominantly during inspiration, primarily in the upper interspaces, whereas the internal intercostals are recruited predominantly during expiration primarily in the lower interspaces.[40] Wilson et al.[38] demonstrated by the application of the reciprocity theorem of Maxwell that the external intercostals in the dorsal portion of the costal interspaces have a large inspiratory mechanical advantage. This advantage decreases in the ventral and caudal directions such that in the ventral portion of the caudal interspaces it is reversed in an expiratory mechanical advantage.[40] Conversely, the internal intercostals in the caudal interspaces have a large expiratory mechanical advantage, but this advantage decreases in the cranial and ventral directions.[40] Because of this pattern of topographic distribution the pattern of neural activation is crucial for the function of these muscles.[40] This pattern was shown to match the pattern of distribution of mechanical advantage, such that the external intercostals have an inspiratory function and the internal intercostals have an expiratory function.[40]

Without question, the levator costae have an inspiratory action on the rib. It is frequently activated even during quiet inspiration in supine dogs.[41] The levator costae's contribution to inspiratory motion of the ribs during quiet breathing, however, appears substantially smaller than that of the parasternal intercostals. This contribution may further increase when the inspiratory motion of the ribs is appreciably increased.

■ The Scalenes

The scalenes run between the transverse process of the five lower cervical vertebrae and the upper margin of the first (scalenus anterior) and second (scalenus medius and posterior) ribs. The action of these muscles is to raise the first two ribs. The orientation of their axis in the neck causes upward motion of these ribs ("pump handle" motion). Moreover, the scalenes are consistently active during quiet breathing in normal individuals and contribute to chest wall expansion.[42] They may be very important in the case of spinal cord injury. When the injury is below C4 to C8, the scalenes' function is entirely or partially preserved, and they contribute importantly to upper rib cage motion in these patients.[43]

■ The Sternocleidomastoids

The sternocleidomastoids run between the mastoid processes of the temporal bone and the manubrium sterni and medial portion of the clavicle. The pressure-generating ability of the sternocleidomastoid muscle in normal humans is about the same as that of the scalene muscles. In humans, these muscles are electrically silent during quiet breathing, but they may be recruited with increased ventilatory load. These muscles are particularly important in high quadriplegics in whom they preserve their function because they are innervated by the 11th cranial nerve and spinal nerves C1 to C2.[33,44] Through training the sternocleidomastoids may develop marked hypertrophy and contribute to several hours of ventilator independence in these patients.[44] They also may be recruited in patients with poliomyelitis and diaphragmatic dysfunction. These muscles are thought to be important in moving the upper rib cage in patients with chronic obstructive pulmonary disease (COPD), even though a clinical experimental study failed to demonstrate consistent activity in these muscles in these patients.[45]

■ The Shoulder Girdle and Neck Muscles

Several shoulder girdle and neck muscles may contribute to inspiration under particular circumstances. Most of these muscles run from the rib cage to an extrathoracic extension. When the rib cage is fixed in the lean-forward position—a position commonly employed by patients with COPD—these muscles contribute to expansion of the rib cage during inspiration. Muscles that may contribute to inspiration include the trapezius, latissimus dorsi, pectoralis major and minor, erector spinae, teres major, serratus anterior, platysma, mylohyoid, and sternohyoid. Since these muscles commonly contribute to inspiration in patients with severe airflow obstruction, their further use for other activities (e.g., hair combing), may considerably increase dyspnea in these patients.[46]

■ The Clavicular Head of Pectoralis Major

The clavicular head of the pectoralis major runs laterally and caudally from the medial half of the clavicle and manubrium sterni to the humerus. If the arms are fixed and braced, contraction causes downward motion of the ribs and sternum, increase in pleural pressure and, hence, expiration. Simultaneously, the lower rib cage and the abdomen move outward. Tetraplegics use this expiratory action when all other expiratory muscles are paralyzed.[47]

■ The Triangularis Sterni

The triangularis sterni is the most important expiratory muscle of the rib cage.[48] The muscle runs at the inside of the thorax between the inner aspect of the sternum and the inner aspect of the five lower ribs (Fig. 3-8), and its action is to lower the ribs relative to the sternum and thus to cause expiration. The triangularis sterni is electrically silent in humans breathing quietly,[48] but it is recruited during expiration below FRC.[48] Its neural activation is also coupled with that of the abdominal muscles.[48] Its recruitment threshold is low, lower than the recruitment threshold of most other expiratory muscles.

■ The Abdominal Muscles

The abdominal muscles are composed of four different muscle layers (Fig. 3-1). Ventrally, a muscular sheet running between the

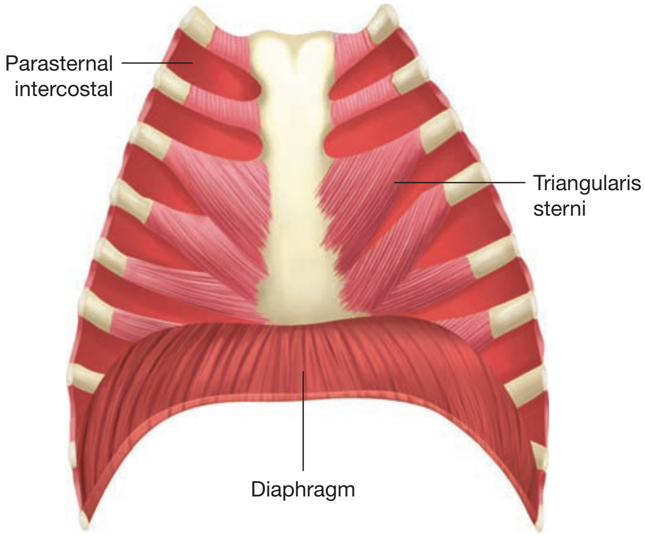

Figure 3-8 Diagram illustrating the functional anatomy of the parasternal intercostal muscles, the triangularis sterni, and the diaphragm.

AL GRAWANY

lower costal cartilages and the sternum and the pubis represents the rectus abdominis. This muscle is enclosed in a sheath formed by the aponeuroses of the other three muscles. Laterally, an oblique muscle runs obliquely downward and forward between the lower eight ribs and the iliac crest, inguinal ligament, and linea alba medially, the external oblique. At the inner surface of this muscle lies the internal oblique with a fiber orientation, which is 90 degrees perpendicular to the external oblique. These muscles are homologous to the external and internal intercostals. The innermost layer is the transversus abdominis, a circular muscular sheet surrounding the abdomen, with a fiber orientation that is parallel to the ribs. The transversus abdominis originates from the inner surface of the lower six ribs, where it interdigitates with the costal insertions of the diaphragm. It runs from this origin and the lumbar fascia, iliac crest, and inguinal ligament, circumferentially around the abdominal visceral mass to terminate ventrally in the rectus sheet. These muscles all have an expiratory action, by virtue of the inward pull of the abdomen they cause and of the insertions they have in the rib cage. In addition, however, rib cage expansion may occur with contraction of some of these muscles through the increase in abdominal pressure accompanying their contraction.[49]

The abdominal muscles are electrically silent during quiet breathing. Usually, however, tonic activity is present in the abdominal muscles in upright position, particularly in the upper segments.[31] During inspiratory loading, CO_2-induced hyperventilation, exercise, and forced expiration, these muscles are recruited. The transversus abdominis appears to have the lowest recruitment threshold.[50,51]

RESPIRATORY MUSCLE INTERACTION

Important interactions among respiratory muscles during quiet breathing are discussed in the following section.

■ Respiratory Muscle Interaction During Quiet Breathing

Respiratory muscle interaction is traditionally studied by means of a Konno–Mead diagram, relating rib cage diameter or cross-sectional area to abdominal diameter or cross-sectional area (Fig. 3-6). First, this relationship is determined in the absence of muscle contraction, during a relaxed expiration, yielding a relaxation line. During quiet breathing in the upright position, the chest wall moves along this relaxation line, which means that proportional expansion of rib cage and abdomen is occurring. In the supine position, abdominal movement is proportionally greater than rib cage movement. Since isolated diaphragmatic contraction in quadriplegics causes abdominal movement without rib cage motion or even inward movement of the upper rib cage (upper rib cage paradox), diaphragmatic contraction alone cannot be responsible for the pattern of motion occurring during quiet breathing (Fig. 3-6). Therefore, this motion requires concomitant contraction of other muscles (i.e., the parasternal intercostals and scalenes). These muscles actively contribute to chest wall motion and cause upper rib cage expansion, whereas diaphragmatic contraction alone would cause upper rib cage paradox. During quiet breathing, the diaphragm probably contributes about 60% to 70% of the tidal volume, and the parasternal intercostals and scalenes contribute the rest.[52]

Posture alters the interaction between the respiratory muscles. For the diaphragm, the resistance of the abdominal contents on diaphragmatic descent is the principal determinant of its action on the rib cage. When changing from a seated to a supine posture in humans, there is a marked increase in abdominal compliance[53] and changes in the diaphragm shape result in less rib expansion. The influence of posture on the lung-expanding action of the diaphragm has been confirmed in patients with upper cervical cord transaction. Indeed, when these patients were supine, the paced diaphragm was able to generate an adequate tidal volume but the latter was progressively and markedly reduced when the patients were gradually tilted head up.[33] The abdominal muscles[54,55] and also the triangularis sterni[48,56,57] are silent in the supine posture in healthy individuals, and while the tonic activity of the abdominal muscles in the standing posture is not related to the phases of the respiration, the activity of the triangularis sterni is confined to expiration.[57] Active use of these two sets of expiratory muscles in the standing posture compensates for the adverse effect of this posture on the inspiratory muscles, in particular the diaphragm.

Sleep affects respiratory muscle function negatively but in healthy individuals these physiologic changes are not clinically significant. Sleep is associated with a generalized postural muscle hypotonia that is most profound during the phasic events of rapid eye movement (REM) sleep.[58] Therefore, respiratory muscles with a dual respiratory and postural function like the intercostals lose activity during REM sleep.[59] However, the diaphragm, which exhibits respiratory and postural function, maintains and even increases its activity to maintain tidal volume during REM sleep.[59] In severe COPD patients where rib cage motion is mainly produced by the inspiratory muscles of the rib cage as the diaphragm is mechanically impaired by hyperinflation, the substantial decrease in the activity of the scalene and sternocleidomastoid muscle during REM sleep is expected to decrease inspiratory pressure development and to lead to hypoventilation.[60]

PHYSIOLOGIC CONDITIONS AFFECTING RESPIRATORY MUSCLE INTERACTION

Respiratory muscle interaction present during quiet breathing and the chest wall motion resulting from it may be altered in a number of physiologic circumstances in which ventilatory load is affected. Indeed, the respiratory muscles participate in tasks that, although not strictly ventilatory in nature, serve important respiratory functions. These tasks of daily life include speech, laughter, swallowing, gagging, vomiting, and coughing. In addition, the interaction of the respiratory muscles is also modified during non-ventilatory tasks.

Speech and laughing require the coordination of respiration and structures involved in producing sound features. Spontaneous speech occurs primarily at volume levels below spontaneous end expiration.[61] There is, therefore, a successive recruitment of muscles of expiration to empty the rib cage: first the triangularis sterni muscle[48,61] and the internal intercostal muscles, then the external oblique and other muscles of the lateral abdominal wall, and finally the rectus abdominis.[50,62,63] At the very end of expiration, the latissimus dorsi is active too.[62,63] Abdominal contraction during speech can optimize the inspiratory function of the diaphragm obliged to contract rapidly between phrases, and will also prevent dissipation of the pressure developed by the rib cage muscles on paradoxical abdominal displacement.[61]

Laughing is a natural maneuver triggered by emotion necessitating the coordination of the laryngeal and respiratory systems to produce a characteristic sound pattern and phasic lung pressure variations superimposed on an active expiratory effort. Laughter generally takes place when lung volume is low, near FRC, and is terminated near residual volume.[64] It is characterized by sudden repetitive expiratory efforts leading to a decrease in lung volume due to sudden and sustained increase in gastric and esophageal pressures. The triangularis sterni muscle is recruited during laughing.[48] Higher transdiaphragmatic pressure at the end of the consecutive expiratory efforts indicates that the diaphragm actively prevents part of the increase in abdominal pressure from being transmitted to the chest wall cavity, thereby protecting intrathoracic structures from further mechanical stress and compression.[64] A pilot study suggests that the pattern of diaphragm activation during laughter is different from that induced by coughing or sneezing.[65]

For swallowing, respiration needs to be interrupted. During swallowing, the passive expiration of the diaphragm is interrupted by static activity aimed at preserving respiratory volume for expiration after swallowing.[66] Abdominal activity increases throughout pre- and post-swallowing expiration.[66]

Vomiting that is produced by changes in thoracic and abdominal pressures is generated by the coordinated action of the major respiratory muscles. During vomiting, the diaphragm and the external intercostal (inspiratory) muscles co-contract with abdominal (expiratory) muscles in a series of bursts of activity culminating in expulsion while the internal intercostal (expiratory) muscles contract out of phase with these muscles during retching and are inactive during expulsion.[67] Finally, the portion of the diaphragm surrounding the esophagus relaxes during expulsion, presumably to facilitate rostral movement of the gastric content.[67]

Coughing, sneezing, and gagging represent complex acts involving both inspiratory and expiratory phases during which most of the respiratory muscles are recruited. Importantly, during those maneuvers, the maximal diaphragm force is reached.[68,69] Voluntary cough in humans is associated with a coordinated activation of the expiratory and accessory muscles. A graded increase in activity and burst duration proportional to cough flow rates is observed. Low cough flow rates are essentially produced by the activation of the expiratory muscles, whereas accessory muscles become involved sequentially and increasingly with the production of higher flow rates.[70] The triangularis sterni muscle is actively recruited during coughing[48,71] and during sneezing.[71]

Finally, understanding the level of muscle recruitment may be particularly relevant when testing respiratory muscle force to evaluate the degree of impairment in some diseases. Indeed, in untrained normal subjects, maximal inspiratory effort against a closed shutter (Müller maneuver or the maximal inspiratory pressure) mainly activates the intercostal muscle and the diaphragm as well as the sternomastoid.[72] The same holds true for the sniff maneuver through the nose.[72] The combined maneuver consisting in a maximal inspiratory maneuver combined with a maximal expiratory effort also activates the expiratory muscles (rectus abdominis) and produces the highest level of diaphragmatic strength as assessed by measuring transdiaphragmatic pressure.[72] The maximal electrical activity of the diaphragm is reached during the sniff maneuver.[72] These data indicate that the pressure generated by these maneuvers reflects a complex interaction between several groups of muscles.

All the above-mentioned effects pertain to ventilatory aspects of the respiratory muscles but, in addition to their respiratory role, the respiratory muscles also contract during postural tasks. The costal and the crural diaphragm are active with a single rapid movement of the contralateral upper limb in humans.[73] Electromyographic activity of the diaphragm increases prior to the onset of the activity of the muscle responsible for movement. This occurs irrespective of the phase of respiration[73] and is associated with an increase in transdiaphragmatic pressure with an initial reduction in length of the costal diaphragm. Similarly, during trunk rotation external and internal intercostal muscles show increased inspiratory activity superimposed on their postural tone[74,75] as do the parasternal intercostals.[76] During repetitive movement, the diaphragm contracts tonically throughout the respiratory cycle and phasic modulation of diaphragm activity at the frequency of limb movement is superimposed on its respiratory and tonic activation.[77] This was also observed in the transversus abdominis muscle.[77] Modulation of the intra-abdominal pressure that occurs through coordinated activity of the diaphragm, abdominal muscles, and pelvic floor muscles may be important for the control of spinal stability when the limbs move.[73,77] When respiratory demand is increased, the activity of the diaphragm and the transversus abdominis associated with movement of an arm is reduced or even abolished, and the associated changes in gastric pressure are reduced.[78] In humans, the postural role of the diaphragm may also be impaired with specific fatigue of the inspiratory muscles.[79] The human triangularis sterni muscle also contracts during postural maneuvers such as head flexion, trunk rotation, and leg lift.[48]

PATHOLOGIC CONDITIONS AFFECTING RESPIRATORY MUSCLE INTERACTION

Respiratory muscle interaction is profoundly affected by a number of pathologic conditions, including hyperinflation and reduction in or loss of muscle activity.

Hyperinflation is a functional abnormality of lung diseases in which airflow obstruction or loss of elastic recoil are features. Hyperinflation may be particularly severe in patients with COPD, in whom the FRC often exceeds predicted total lung capacity (TLC). An overwhelming amount of evidence shows that hyperinflation reduces the diaphragmatic effectiveness as a pressure generator and reduces diaphragm contribution to chest wall motion. The contribution of the intercostal muscles and scalenes is likely to be increased, such that chest wall motion becomes exclusively or predominantly rib cage motion (Fig. 3-6). The ineffectiveness of the diaphragm may result from diaphragmatic shortening, geometric alterations, alterations in diaphragm–rib cage interaction, alterations in mechanical arrangements among the costal and crural parts of the diaphragm, and reduction in the zone of apposition.[80] Among these, diaphragmatic shortening appears to be the most important. Indeed, with inflation from FRC to TLC, the diaphragm shortens about 30% to 40%,[21,22] whereas the parasternal and upper external intercostal muscles shorten by only 10%,[23,81] the scalene by 2%,[82] and the sternomastoid muscle by 6%.[82] For the diaphragm, this shortening is expected to reduce significantly its pressure-generating capacity. Several studies indicate that diaphragmatic geometry is not affected significantly by hyperinflation, pointing out that the length–force properties of the diaphragm represent the most important factor for the pressure-generating capacity of this muscle.[83,84] The appositional component of diaphragmatic action is reduced substantially due to a reduction in the zone of apposition.[32] The insertional component is affected so that diaphragmatic contraction causes inward retraction of the lower rib cage. This may be noticed clinically in patients with severe hyperinflation.[85,86] The mechanical arrangement between the costal and crural parts of the diaphragm changes from a parallel arrangement at FRC to a series arrangement at TLC.[21] This is likely to further compromise the pressure-generating capacity of the diaphragm independently of its force–length characteristics.

Hyperinflation also impairs the pressure-generating capacity of the inspiratory intercostal muscles (the parasternals and the external intercostals). This effect is mainly related to the orientation and motion of the ribs.[27] The synergistic interaction between the diaphragm and the inspiratory intercostal muscles becomes prominent at high lung volumes.[27] The force-generating capacity of the neck muscles like the scalene and the sternomastoid muscle is maintained with hyperinflation.[82] During exercise, dynamic hyperinflation brings end inspiratory lung volume close to total lung capacity and reduces inspiratory reserve volume. Consequently, patients develop a rapid and shallow breathing pattern. Impairments in dynamic respiratory muscle function might further exacerbate the rapid and shallow breathing of these patients during exercise by promoting further restriction of tidal volume expansion.[87] With increasing lung hyperinflation in COPD patients, the inspiratory muscles of rib cage and accessory respiratory muscles are increasingly recruited even at relatively low work rates.[88] It has also been observed that during exercise, there is a progressive increase in total inspiratory pressure contribution from rib cage and accessory muscles relative to that of the diaphragm, and the magnitude of this increase appears to depend on the non-diaphragmatic muscle reserves during resting breathing.[89] These alterations in respiratory muscle recruitment pattern might contribute to exercise limitation and might necessitate the application of specific therapeutic strategies.[90] It has been suggested that in severe COPD patients, improving rib cage and accessory inspiratory muscle function should be a priority.[88] It has been demonstrated that respiratory muscle resistance training can provide a strong training stimulus specifically to the rib cage and accessory inspiratory muscles in these patients, with diaphragm activation being similar to that during exercise hyperpnea.[91] In dogs, hyperinflation induces lengthening of the abdominal muscles, particularly the transverse abdominis and internal oblique muscle.[92] Consequently, the rise in abdominal pressure obtained by selective stimulation of the abdominal muscles at TLC is greater than that obtained at FRC.[93] This also happens in normal humans during magnetic stimulation of the abdominal muscles.[92]

It should be emphasized, however, that the above pertains to acute hyperinflation. In chronic hyperinflation, the diaphragm adapts to the chronically foreshortened state by dropping out of sarcomeres.[15] As a consequence, the filament overlap within each sarcomere is restored toward optimal overlap. This adaptation is shown in Figure 3-2. This adaptation, however, only partially restores diaphragmatic function—first, because part of the reduction in force with shortening is due to compression of the T-tubular system, blocking exit-electrolyte flow and impeding excitation–contraction coupling.[16] Whether adaptations in T-tubular function also occur with chronic foreshortening remains to be investigated. Second, sarcomere adaptation adapts only to the loss in diaphragmatic function associated with diaphragmatic shortening and not to the loss in function due to geometric alterations, alterations in diaphragm–rib cage interaction, changes in mechanical arrangement among different parts of the diaphragm, or loss of zone of apposition. Third, although sarcomere adaptation restores the force-generating capacity of a foreshortened diaphragm, it reduces the number of sarcomeres in series. Consequently, sarcomere adaptation compromises the capacity of the diaphragm to undergo changes in length and, hence, its capacity to produce volume changes, presumably its most important function. The fiber length of the parasternal intercostal muscles[94] and of the scalenus muscle[95] are, however, not affected by chronic hyperinflation in animals.

Interventions aimed at reducing hyperinflation such as lung volume reduction surgery (LVRS) and lung transplantation improve diaphragmatic function.[96] The effects of LVRS are primarily due to an increase in the zone of apposition, lengthening of the diaphragm, and improved neuromechanical coupling.[97] To what extent complete sarcomere adaptation is present in patients with COPD and extreme hyperinflation is not clear from the clinical studies with LVRS. After lung transplantation the radius of curvature and the zone of apposition of the diaphragm are restored. This is primarily due to mediastinal displacement toward the graft.[96]

Expiratory muscle recruitment is frequently observed in COPD patients with severe airflow obstruction both at rest and during exercise.[98,99] The transversus abdominis is frequently recruited. Expiratory muscle recruitment may contribute to the intrinsic positive end-expiratory pressure ($PEEP_i$) that is frequently observed in these patients. $PEEP_i$ is primarily caused by impaired pulmonary mechanics and consequent dynamic hyperinflation.[100] The functional significance of this expiratory muscle activation is poorly understood. Indeed, in severe airflow obstruction, expiratory flow limitation is frequently present. In the presence of expiratory flow limitation, recruitment of expiratory muscles no longer contributes to expiratory flow. Whether excessive expiratory muscle activation during exercise might contribute to symptoms and exercise limitation in these patients is still a matter of debate.[99,101]

In patients with pulmonary disease in general and COPD in particular, several factors may contribute to generalized muscle weakness, in which the respiratory muscles partake. These include hypoxemia and hypercapnia, malnutrition, cardiac failure, corticosteroid treatment, infection, electrolyte disturbances, and inactivity with consequent disuse atrophy.[102] There is consensus that COPD exacerbations contribute to the development of this muscle weakness.[103] Of particular importance appears to be treatment with corticosteroids in repetitive bursts, which is often inadvertently administered to COPD patients. Typically, this causes a myopathic pattern characterized by scattered necrotic fibers with an increased number of central and subsarcolemmal nuclei, and generalized muscle fiber atrophy as seen on muscle biopsy[104] instead of selective type IIb fiber atrophy as is seen in animal studies.

The continuous patterns of motor activity associated with respiration make the diaphragm the most active muscle in the body. The daily duty cycle (ratio of active to inactive time) of the diaphragm in most species is about 45% compared to 2% for the extensor digitorum muscle (predominantly composed of type IIb fibers) and 14% for the soleus muscle (mainly a type I muscle).[105] Given that the diaphragm is highly active, it is expected to be particularly sensitive to inactivity. It is therefore not surprising that serious diaphragm dysfunction develops rapidly during controlled mechanical ventilation, a situation in which the diaphragm is totally inactive.[106–108] Perturbations in respiratory muscle interaction are also marked in patients with cervical spinal cord injuries. In these patients, the intercostal and abdominal muscle contribution to respiratory function is lost. Diaphragm inspiratory capacity is also often compromised when injury is located at the C3 to C5 levels. During quiet breathing, tetraplegic subjects with injuries at C4 to C7 use their scalene[43,109] that becomes hypertrophied.[109] Patients with high tetraplegia use several neck muscles[44] in addition to the sternocleidomastoids and trapezii to breathe.[33] Quadriplegics are also predisposed to the development of inspiratory muscle fatigue because of reduced muscle strength and endurance.[110] Inspiratory muscle training in these patients increases both strength and endurance and protects against fatigue.[110] Diaphragm contracting alone through phrenic nerve pacing in subjects with upper cervical cord transaction or during spontaneous breathing in subjects with traumatic lower cervical cord transaction exerts both an expiratory action on the upper rib cage and an inspiratory action on the lower rib cage.[33,35,43] Finally because abdominal and expiratory rib cage muscles are paralyzed in subjects with tetraplegia, their ability to raise intrathoracic pressure is markedly reduced. Despite active use of the clavicular portion of the pectoralis major to deflate the rib cage during forced expiration,[47,111,112] cough is ineffective, and the clearance of airway secretion is markedly impaired. Strength training of the pectoralis major improves expiratory function,[113] an effect that is expected to increase the effectiveness of coughing that might reduce the prevalence of bronchopulmonary infections in these subjects.

CONCLUSIONS

The act of breathing requires the coordinated action of a number of muscle groups. During quiet breathing, chest wall motion results from the action of the diaphragm but also from the other inspiratory muscles such as the parasternal intercostals and the scalenes in addition to the expiratory muscles. Those respiratory muscles are all well equipped to sustain continuous rhythmic contraction. Respiratory muscle interaction is affected by posture and sleep but also in a number of physiologic circumstances in which ventilatory load is altered, such as during speech, laughter, swallowing, gagging, vomiting, and coughing. In addition to their respiratory role, the respiratory muscles also contract during postural tasks such as limb muscle movement, leg lift, trunk rotation, and head flexion. Finally, several pathologic conditions including hyperinflation, reduced or loss of activity caused by undernutrition, medical treatment (in particular corticosteroids), mechanical ventilation, or spinal cord injury also may affect the function and the interaction of the respiratory muscles. Strategies consisting of reducing hyperinflation (e.g., LVRS, lung transplantation) or improving muscle function through muscle training may help to some extent in restoring respiratory muscle function.

ACKNOWLEDGMENTS

The authors thank Mr. Jean Sente for making excellent drawings. They further thank the Fonds voor Wetenschappelijk Onderzoek-Vlaanderen grants #G.0389.03, #G.0386.05, and #G.0197.07, Research Foundation KU Leuven grants #OT/02/44 and #OT/06/52, and Astra Zeneca Pharmaceuticals for their support of the research mentioned in this chapter.

CHAPTER 4

Molecular Regulation of Lung Development

Wellington V. Cardoso
Ying Yang
Jining Lu

INTRODUCTION

This chapter focuses on the mechanisms that control the development of the respiratory system from specification of the progenitors of the primordial lung to the formation of the definitive alveoli. The respiratory system is characterized not only by its major diversity in cellular phenotypes, but also by its complex 3D architecture in both the airway and alveolar compartments designed to conduct air and facilitate gas exchange. Its network of conduits comprises the trachea and extrapulmonary and intrapulmonary airways formed by multiple generations of branching epithelial tubules.

Development of the respiratory system encompasses prenatal and postnatal life, but timing and duration of specific events can vary substantially among species. Lung development starts much earlier in humans than in mice and rats; alveolar formation initiates in the human lung by late gestation in contrast to the murine lung, in which it is a postnatal process (Fig. 4-1). As an organ of exceptional structural and functional complexity, the lung is formed by a contribution of all embryonic layers, including the endoderm (epithelium), mesoderm (mesenchyme), and ectoderm (innervation).

Based essentially on histologic criteria, lung development has been traditionally described in four stages: (1) *Pseudoglandular*: corresponding to the initial period of formation of the bronchial tree, when the lung exhibits a gland-like morphology with epithelial tubules separated by a thick mesenchymal layer; (2) *Canalicular*: when airway branching is nearly finished and distinct columnar and cuboidal epithelial cells are seen in proximal (large) and distal (small) airways, respectively. The epithelial tubules are then separated by a thinner mesenchyme containing blood vessels; (3) *Saccular*: primitive saccules are seen at the distal end of bronchial tree with widening of the lumens and the appearance of flat-shaped type I (AT1) and cuboidal, surfactant-producing type II (AT2) cells. The intimate approximation of the type I cell to the vascular structures (primitive alveolo-capillary barrier) allows gas exchange during the immediate postnatal period; and (4) *Alveolar*: when these primitive saccules undergo secondary septation to form numerous smaller mature alveolar structures to increase the gas-exchange surface.[1,2]

HOW RESPIRATORY PROGENITORS ARISE

The lung originates from the anterior portion of the gut tube (foregut), which also gives rise to organs, such as the thyroid, stomach, liver, and pancreas.[3,4] Respiratory progenitors of the lung and trachea arise from the ventral foregut endoderm in mice at around embryonic day 9 (E9.0, mid-gestation) and in humans around the 4th week of gestation. These cells can be readily recognized even before a lung primordial bud forms by the expression of Nkx2-1 (Ttf1, thyroid transcription factor 1); this gene, however, is not lung-specific, and it labels progenitor cells of the thyroid located in more anterior (cranial) regions of the foregut (Fig. 4-2).[5] An Nkx2-1 lineage tracing study reveals that these Nkx2-1+ progenitors at E9.0 give rise to the vast majority of lung epithelial cells.[6] Nkx2-1 is essential for the lung, as disruption of this gene in mice results in severely hypoplastic cystic lungs and inability of airways to form branches. Importantly, in mutants there is no evidence of epithelial cells expressing surfactant protein or other differentiation markers typically found in the lung.[5] It is unclear whether these mutants' lung progenitors are never specified or just cannot be maintained in the absence of Nkx2-1.

How are these progenitors specified? In vivo and in vitro studies in different species point to an interplay between multiple endodermal and mesodermal signals in the foregut, but notably WNT is found to be crucial in this process. Both WNT2 and WNT2B are present in the foregut mesoderm while β-CATENIN (CTNNB1) is present in both mesoderm and endoderm at the prospective site of lung formation. Loss of canonical WNT signaling prevents the appearance of Nkx2-1-expressing lung progenitor cells.[7,8] The significance of this pathway

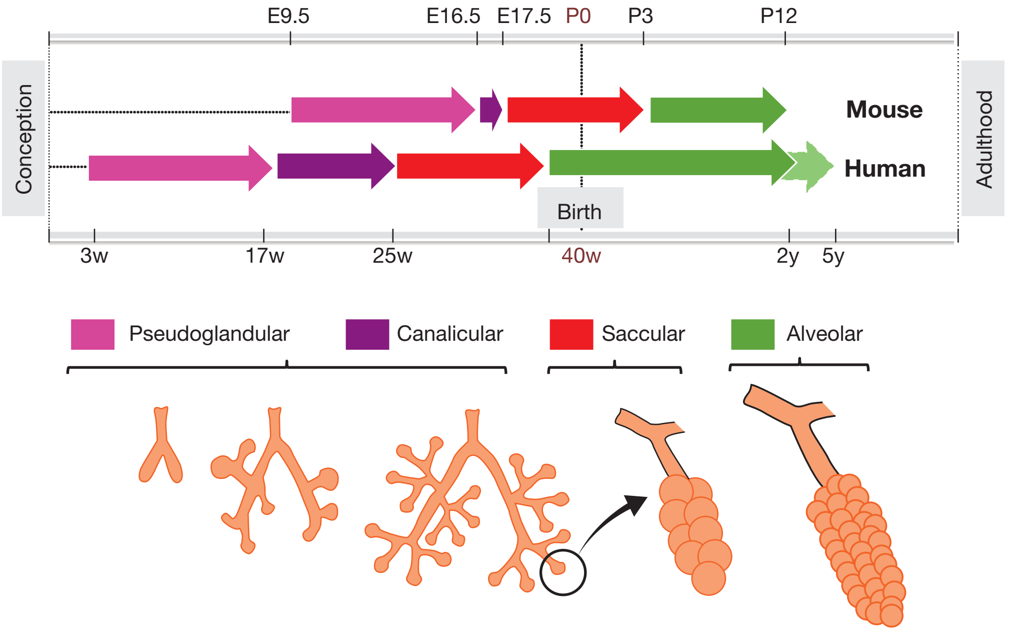

Figure 4-1 Timeline for the developmental stages of mouse and human lungs and diagram of representative stages. Mouse (E, embryonic or P, postnatal days); humans (w, gestation week; y, year).

is further confirmed by the expansion of the Nkx2-1 lung domain to more posterior sites when WNT/β-CATENIN signaling is overactivated in the foregut endoderm.[7,8] Sonic hedgehog (SHH), a member of the hedgehog family of proteins, and its transducing molecules Patched (PTC) and GLI1/2/3, also are present in the lung domain of foregut in the endoderm and mesoderm, respectively. Gli2/3 double knockout results in failed induction of respiratory progenitors.[9] Moreover, there is a role for bone morphogenetic protein (BMP) signaling in regulating the expression of Sox2, which is required for proper foregut patterning and the expansion of Nkx2-1-expressing lung progenitors.[10]

Interestingly, the vitamin A derivative retinoic acid (RA) serves as a core signal bridging WNT, SHH, and BMP pathways. RA synthesis and receptor (RAR) activity are prominent in the E8.5–9.5 mouse foregut.[11] The importance of RA in lung development has been recognized for decades from lung agenesis and developmental abnormalities due to vitamin A deficiency or due to genetic disruption of key components of the RA pathway.[12–15] There is accumulated evidence that lung agenesis is due to the inability to specify and expand the lung progenitors in the absence of RA signaling. RA was shown to be required for lung specification through a mechanism that involves RA induction of SHH, which then acts in the foregut mesoderm inducing WNT2/2B.[16]

FORMATION OF THE LUNG AND TRACHEAL PRIMORDIA

Once specified, these Nkx2-1-expressing respiratory progenitors are subsequently expanded to generate the tracheal and the lung primordia. The primordial lung is identified in human embryos at the beginning of gestation (4th week), much earlier compared with mice (mid-gestation at E9.5). Lung buds arise as lateral outgrowth of the ventral foregut endoderm and fuse at the midline, where the tracheal primordium forms (Fig 4-2B–D). From then on, the trachea and the

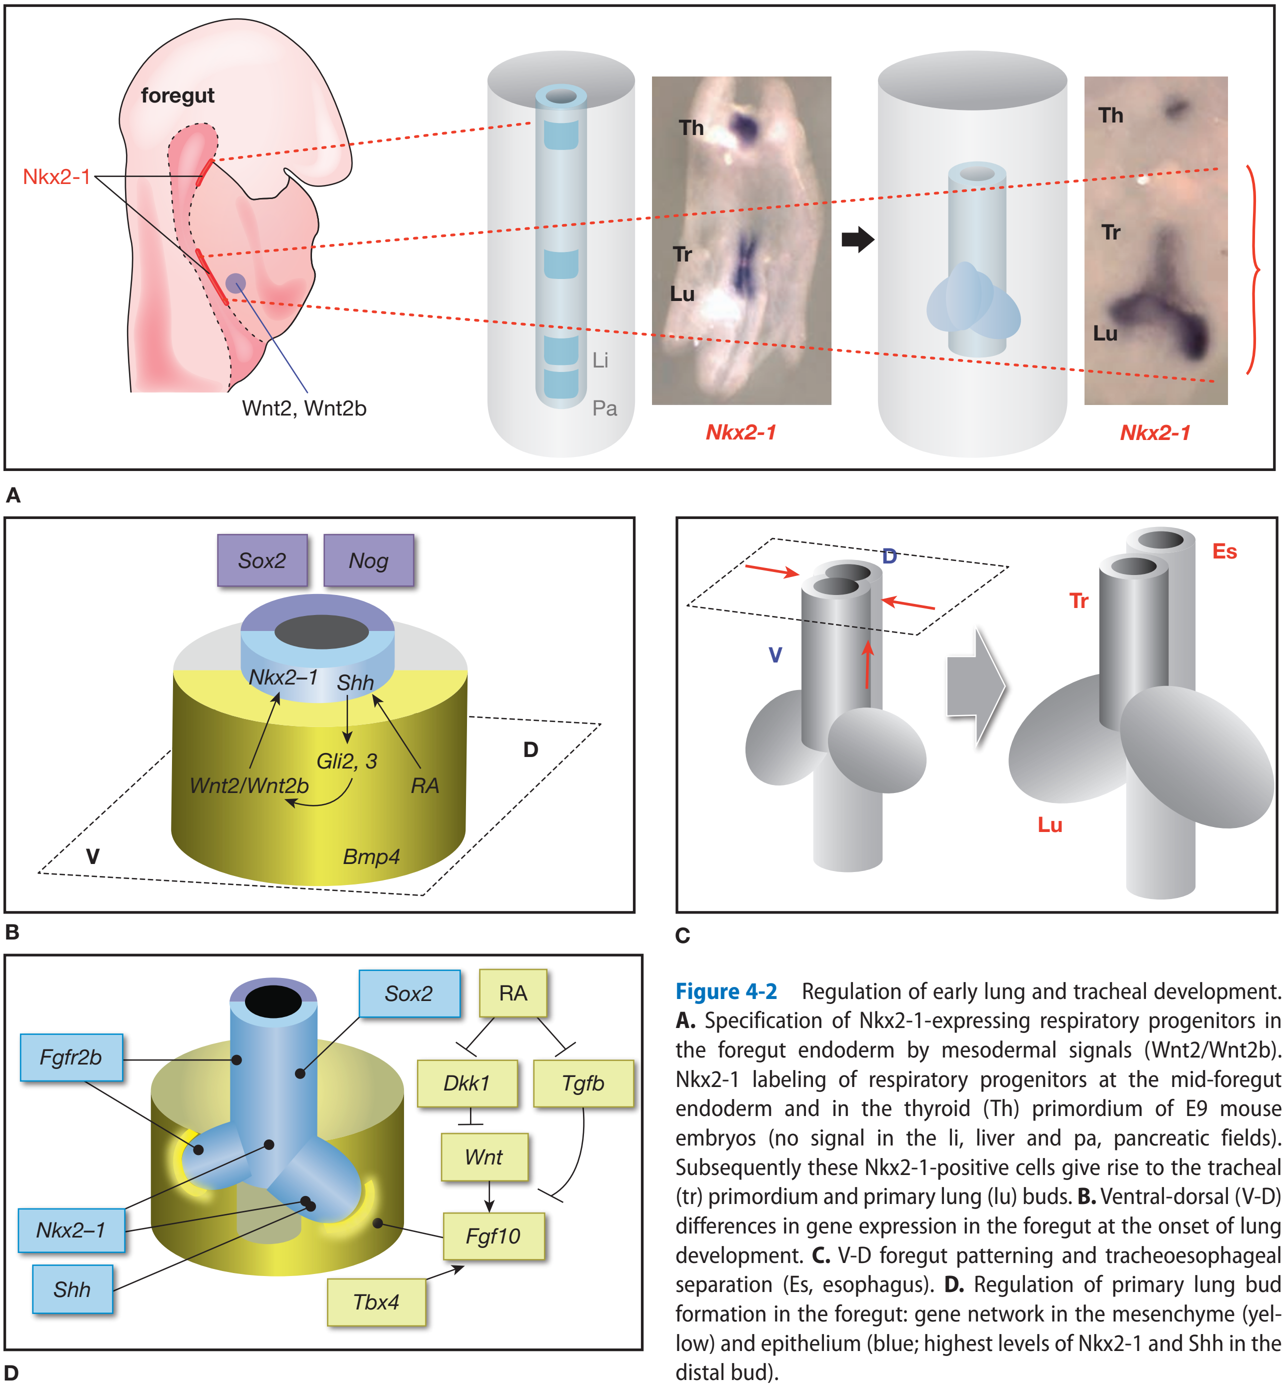

Figure 4-2 Regulation of early lung and tracheal development. **A.** Specification of Nkx2-1-expressing respiratory progenitors in the foregut endoderm by mesodermal signals (Wnt2/Wnt2b). Nkx2-1 labeling of respiratory progenitors at the mid-foregut endoderm and in the thyroid (Th) primordium of E9 mouse embryos (no signal in the li, liver and pa, pancreatic fields). Subsequently these Nkx2-1-positive cells give rise to the tracheal (tr) primordium and primary lung (lu) buds. **B.** Ventral-dorsal (V-D) differences in gene expression in the foregut at the onset of lung development. **C.** V-D foregut patterning and tracheoesophageal separation (Es, esophagus). **D.** Regulation of primary lung bud formation in the foregut: gene network in the mesenchyme (yellow) and epithelium (blue; highest levels of Nkx2-1 and Shh in the distal bud).

digestive tube separate through a mechanism still poorly understood that involves formation of a tracheo-esophageal septum.[17,18] Primary lung bud formation is crucially dependent on the local expression of Fgf10 in the foregut mesoderm.[19,20] FGF10 diffuses to the nearby endoderm at the prospective lung region and activates FGFR2b signaling in Nkx2-1-expressing progenitor cells, leading to epithelial proliferation and migration toward the FGF10 source.[21,22] Fgf10 null mice fail to form lungs and die at birth. Interestingly, the trachea still forms in these mutants, suggesting that Nkx2-1-expressing progenitors from the lung and trachea have different requirements for FGF10 signaling for expansion or survival.[19,20]

Evidence suggests that RA signaling is highly active in the foregut at the onset of lung development, integrating multiple pathways that control Fgf10 expression to form the lung primordium. RA ensures proper levels of FGF10 in the lung region by balancing the activity of WNT and TGF-β in the foregut mesoderm. RA controls expression of the WNT inhibitor Dkk1, thus allowing WNT induction of FGF10.[23,24] This is further supported by the inability of Wnt2a/Wnt2b null mice to induce FGF10 in the foregut.[7] Moreover, RA prevents the widespread activation of TGF-β signaling in the foregut mesoderm, which suppresses Fgf10 expression (Fig. 4-2D). Thus, the disruption of WNT/TGF-β/FGF10 interactions represents an additional mechanism to explain the failure to form the lungs classically reported in vitamin A deficiency.

Members of the T-box family of transcription factors (Tbx2–Tbx5) have been reported in the developing foregut and lung mesenchyme.[25] Studies in chick embryo show that Tbx-4 is co-expressed with Fgf10 in the foregut at the onset of lung development. Notably, Tbx4 can induce Fgf10 expression and consequently expand the domain of Nkx2-1-expressing respiratory progenitors at the onset of lung development.[26] Moreover, genetic studies in mice showed a dose-dependent activity of Tbx4 and Tbx5 in regulating primary bud formation, likely through regulation of FGF10 and WNT.[27]

VENTRAL-DORSAL (V-D) PATTERNING AND TRACHEOESOPHAGEAL SEPARATION

Differences in V-D cell fate are already obvious in the foregut at the onset of lung development (Fig. 4-2). The ventral endoderm (respiratory progenitors) expresses Nkx2-1 while the dorsal endoderm (esophageal progenitors) maintains high levels of SOX2 (SRY-box-containing gene 2).[5,28] However, SOX2 inhibition leads to expansion of the NKX2-1 domain and respiratory fate dorsally, towards the esophageal domain.[28] A proper balance between BMP4, expressed ventrally, and its antagonist NOGGIN, expressed dorsally in the foregut, also significantly influences V-D patterning.[10] Conditional deletion of both Bmpr1a and Bmpr1b leads to expansion of a dorsal cell population marked by Sox2 at the cost of the ventral population of NKX2-1-positive cells.[10] NOGGIN has been proposed to protect the dorsal endoderm from the ventralizing effects of BMP4.[29]

An initially single-lumen foregut starts to separate into the ventral trachea and dorsal esophagus as early as E9.5, and it is completed by E11.5. A "splitting and extension model" has been proposed based on live imaging of foregut cultures. The separation initiates from the site of lung bud outgrowth with a saddle-like structure moving anteriorly and a nascent trachea and esophagus extending posteriorly. This mechanism ultimately separates the respiratory from the digestive tract.[30] Alternative models include the fusion of endodermal ridges in the midline[18] and extension of a tracheoesophageal septum by formation of a mesenchymal condensation.[31] The precise mechanisms regulating these events await further in vivo evidence and genetic analyses. A midline epithelial population that co-expresses Sox2, Nkx2-1, and the LIM Homeobox 1 (Isl1) has been recently characterized as a key player in controlling tracheoesophageal separation. These triple-positive cells locate at the dorsal–ventral boundary, and they contribute to both tracheal and esophageal epithelium during the separation.[32] Failure of this separation results in tracheoesophageal fistula, a relatively frequent condition in neonates with high morbidity. This defect has been observed as part of the phenotype of several mouse mutants. Examples include the Shh$^{-/-}$, Nkx2-1$^{-/-}$, Sox2-conditional mutants, Isl1$^{-/-}$ and Gli2$^{-/-}$; Gli3$^{+/-}$ and the RARα$^{-/-}$; RARβ$^{-/-}$ mice.[5,9,28,33,34]

BRANCHING MORPHOGENESIS: FORMATION OF THE BRONCHIAL TREE AND PATTERNING

The bronchial tree forms through a reiterative process of growth and budding of the epithelial tubules collectively termed *branching morphogenesis*. This process initiates after secondary buds form from the lung primordium in mice at E10.5. At this time the pattern of lobation of the right and left lungs also is established. The lungs are asymmetric with respect to their right and left axis and their number of lobes varies according to the species. For example, mouse lungs have one left lobe and four right lobes. It is thought that this asymmetry is regulated by left–right (L–R) determinants as part of an early global program of axis specification. Among the signals involved in this process are TGF-β-related molecules, such as activin receptor II, Lefty1 and 2, and growth differentiation factor 1 (Gdf1), as well as paired-like homeodomain transcription factor 2 (Pitx2).[35–39] Loss of left-right asymmetry resulting in equal number of lobes in both sides is called pulmonary isomerism and is found in several human conditions such as primary ciliary dyskinesia (Kartagener Syndrome).[40,41]

Analysis of the three-dimensional branching pattern of embryonic mouse lungs suggests that the bronchial tree is generated by three geometric branching modes: domain branching, planar bifurcation, and orthogonal bifurcation, following three sequential orders.[42] All modes are used concurrently during development of the bronchial tree and strongly suggest that distinct genetically encoded pathways control each branching model. It is likely that these branching modes are also used in the developing human lungs, but this has not been yet demonstrated.

The mechanism generating new buds during branching morphogenesis is similar to that of primary bud morphogenesis and relies on local epithelial activation of FGFR2b signaling by mesenchymal FGF10 at the sites of budding.[21,22] Perturbations in levels or distribution of FGF10 have a major impact in airway morphogenesis and result in smaller than normal hypoplastic lungs. Reduced number of branches, among other patterning abnormalities, is found in Fgf10 hypomorphic mice (Fgf10$^{lacZ/-}$).[43] During branching morphogenesis Fgf9 expressed from the pleura and transiently from the distal epithelium expands a population of Fgf10-expressing distal mesenchyme (Fig. 4-3A). Mice deficient in Fgf9 have reduced mesenchymal cell population and Fgf10 expression. This leads to disruption of branching morphogenesis and hypoplastic lungs.[44] Recent studies challenge the paradigm that bud formation is strictly dependent on the localized expression of Fgf10. Budding occurs in mesenchyme-free cultures despite the uniform widespread availability of FGF10 in the culture media.[45] Additionally, expression of an Fgf10 transgene in the mesenchyme of Fgf10 knockout mice in vivo partially rescues branching morphogenesis despite its ubiquitous distribution, suggesting a permissive rather than an instructive role for FGF10 signaling.[46]

The size and shape of the growing buds is controlled dynamically by feedback loops established by FGF activity within the epithelium or by exchange of signals between the bud epithelium and the adjacent mesenchyme. For example, high FGFR2 activity in the emerging bud induces expression of its target Sprouty 2 (Spry2) in the distal epithelium. SPRY2, a highly conserved cysteine-rich protein, negatively regulates the FGF-mediated activation of receptor tyrosine kinase signaling in the epithelial bud and thus inhibits bud growth (Fig. 4-3A).[47–50]

Several molecules have been implicated in epithelial-mesenchymal crosstalks that control lung budding. For example, in the developing lung Shh is expressed predominantly at the tip bud epithelium, acting in the lung mesenchyme via Patched (PTC)/

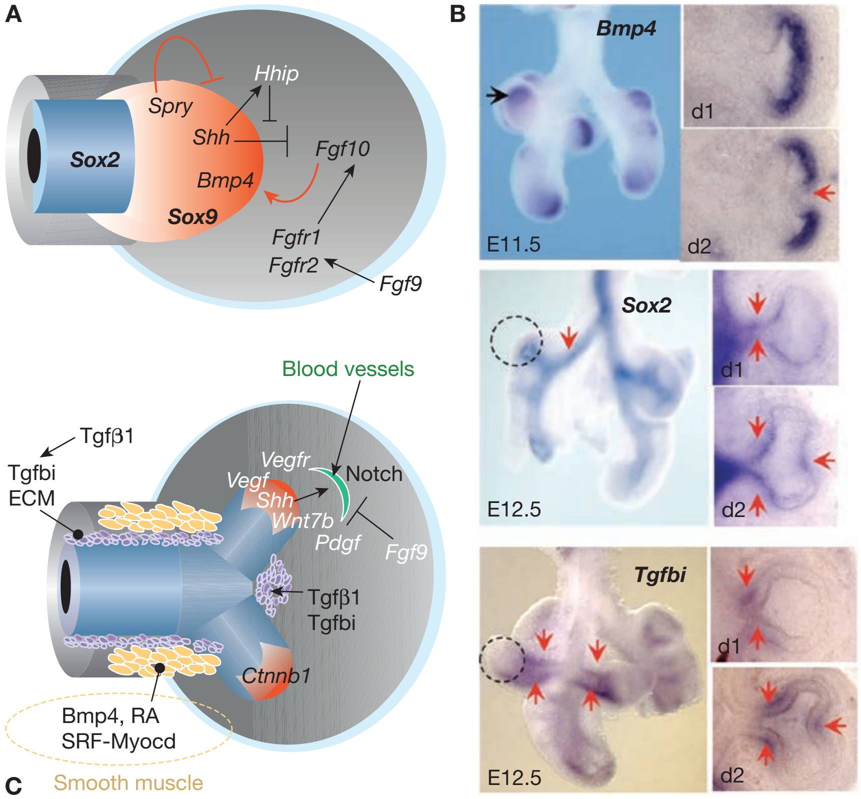

Figure 4-3 Regulation of lung branching morphogenesis, proximal-distal (P-D) patterning and differentiation. **A.** Gene network regulating lung bud elongation. Bud outgrowth is restricted by Fgf10 induction of Bmp4 and Spry2; Spry2 inhibits epithelial Fgf signaling; Bmp4 inhibits epithelial proliferation; Shh inhibits Fgf10 expression through activation of Ptc/Smo signaling. Shh signaling is inhibited by Hhip through a feedback loop. **B.** ISH of Bmp4, Sox2, and Tgfβi during branching (E11.5–E12 in vivo and in lung cultures 24–48 h). Bmp4 labels distal epithelial buds while Sox2 marks the epithelium in stalk and non-branching proximal regions; Tgfβi labels newly formed stalks and proximal mesenchyme. **C.** Airway branching and differentiation of mesenchymal components. Localized Tgfβ activity promotes local ECM deposition and cleft formation. Airway and vascular SM requires the input of Shh, Wnt, Vegf, Pdgf, Notch, and Fgf.

Smoothened (SMO)/GLI (1,2,3) proteins critical for survival of mesenchymal cells.[51–53] However, SHH signaling also has a key role as a negative regulator of Fgf10 expression,[51,54] in distal mesenchymal cells, inhibiting bud outgrowth during airway branching (Fig. 4-3A). In Shh null mice, there is increased expression of Fgf10 transcripts and generalized activation of FGFR2b in the lung epithelium, resulting in severely disrupted branching morphogenesis and cyst-like lungs.[33,53] Increased FGF10-FGFR2 signaling in distal buds is responsible for the high local expression of Shh through activation of Etv transcription factors (Etv4 and Etv5), downstream targets of FGF, establishing an FGF-SHH feedback loop.[55] The high SHH activity in the lung mesenchyme can be negatively controlled by induction of the SHH target Hhip1 (Hedgehog interacting protein) (Fig. 4-3A). HHIP1 binds to and sequesters SHH ligand preventing it from activating signaling in the mesenchyme to repress Fgf10. In Hhip1 null mice, SHH activity is aberrantly increased, leading to decreased Fgf10 expression and disruption of branching morphogenesis.[56] Moreover, FGF10 protein distribution and receptor binding can be modulated by FGF interactions with heparan sulfate (HS) proteoglycans. Disrupting HS expression or altering HS sulfation prevents FGF10 from inducing local responses and can markedly alter lung pattern formation in lung explant cultures.[57,58]

Another mechanism contributing to airway branching is cleft formation. Here extracellular matrix (ECM) is deposited at branch points, accumulating in the epithelial-mesenchymal interface and preventing local expansion of the epithelium. Clefting has been classically associated with local activity of TGF-β signaling in the distal lung (Fig. 4-3). Members of the TGF-β subfamily TGF-β1, 2 and 3, and their receptors (TGFBR1 and TGFBR2) and transducing proteins (SMAD 2, 3), are expressed in different compartments and in a complex pattern during branching morphogenesis. TGF-β1 transcripts are distributed throughout the lung mesenchyme; however, TGF-β1 protein accumulates in regions between buds and along proximal airways, where ECM components (collagen I and III and fibronectin), which are also TGF-β targets, are abundant.[59] The dynamic activity of TGF-β during branching is best visualized by expression of its target gene Tgfbi (Tgfb-induced or BigH3) in the mesenchyme associated with stalk region of growing buds[60] (Fig. 4-3B–C). Treatment of embryonic lungs in culture with TGF-β1 dramatically inhibits branching morphogenesis.[54,61,62] Epithelial activation of TGF-β signaling represses growth and differentiation. Moreover, TGF-β1 exerts important effects in the lung mesenchyme, where it induces expression of ECM components and inhibits Fgf10 expression.[54,63,64] Analysis of organogenesis in TGF-β1-null mice has been largely inconclusive apparently due to rescue by maternal transfer of Tgfb1.[65] The importance of TGFBβ signaling for lung morphogenesis has been demonstrated in Tgfbr2-deficient mice.[66] Both TGF-β2 and TGF-β3 are expressed in the developing lung but neither one seems to be required prenatally. By contrast, mice deficient in these genes die postnatally with collapsed lungs.[67,68]

There is evidence that small non-coding regulatory RNAs are part of the regulatory networks controlling lung development. miRNAs are endogenous small noncoding RNAs that regulate target gene expression post-transcriptionally and play important roles in diverse biological processes.[69–72] Individual miRNAs may target multiple mRNAs; conversely, individual mRNAs may contain sequences complementary to multiple miRNA family members.[73] The importance of the miRNA pathway in lung development was demonstrated by the epithelial deletion of Dicer, the key enzyme that processes microRNA precursors into mature miRNAs. Loss of Dicer in the mouse lung epithelium results in drastic arrest of branching morphogenesis and increased epithelial cell death.[74] The increased levels of FGF10, BMP4, and SPRY-2 in these mutant lungs suggested that the miRNA pathway represses expression of these genes during epithelial–mesenchymal interaction.[74] In humans, Dicer mutation has been linked to pleuropulmonary blastoma, a rare pediatric tumor that arises during fetal lung development.[75] Loss of Dicer1 in the developing lung epithelium alters miRNA-dependent regulation of diffusible growth factors, specifically the miR-140-FGF9 pathway, which promotes proliferation of both epithelial and mesenchymal cells.[76]

AL GRAWANY

ESTABLISHMENT OF PROXIMAL-DISTAL (P-D) CELL FATE

During lung development, the appearance of distinct fates in epithelial progenitors along the P-D axis is tightly coupled with branching morphogenesis. This process is highly dynamic and establishes a SOX9+ distal and a SOX2+ proximal domain to become later the alveolar and airway compartments, respectively. Lineage tracing analyses of epithelial progenitors in the distal compartment (SOX9+ also identified by ID2) shows that they are actually multipotent and able to generate cell types of both the alveolar and the SOX2+ intrapulmonary airways.[77,78] By contrast, extrapulmonary airways, including the trachea, originate from a different progenitor, labeled by p63, a transcription factor from the p53 family of genes.[79]

Canonical WNT and BMP signaling have been implicated as major regulators of P-D cell fate in the lung epithelium. WNT ligands, receptors (Frizzled), and β-catenin are widely expressed in the developing lung but show distinctive distribution in both epithelium and mesenchyme (*web.stanford.edu/group/nusselab/cgi-bin/wnt/*).[80–82] High activity of WNT signaling reporter (TOPGAL), nuclear-localized β-CATENIN, and TCF/LEF transcripts is found in the distal lung buds undergoing branching.[83,84] Targeted disruption of β-catenin or overexpression of the WNT inhibitor Dickkopf 1 (Dkk1) in the distal lung epithelium inhibits distal cell fate and bud formation and proximalizes the lung, a phenotype characterized by proximal epithelial phenotypes extending ectopically to distal sites.[85,86] Conversely, activation of canonical WNT signaling throughout the lung epithelium inhibits Sox2 expression and leads to the appearance of distal fates in proximal airways.[87,88] Thus, canonical WNT plays a key role in the establishment and maintenance of distal cell fates.

Distal epithelial cell fate is also crucially dependent on the BMP pathway. Transgenic mice expressing BMPR antagonists (Xnoggin, Gremlin) in lung epithelial progenitors fail to properly form the distal lung and show proximalization.[89,90] During branching morphogenesis, Bmp4 is expressed in epithelial progenitors at the tip of growing buds and acts locally through autocrine activation of BMPR-SMAD signaling.[91] In lung bud tip organoid cultures, SMAD activation by exogenous BMP4 and TGF-β1 promotes specification of P63+ airway progenitors.[92] BMP4 has been shown to antagonize the proliferative effects of FGF10 in the distal epithelium.[93] and TGF-β1 inhibits Id2 to facilitate differentiation in airway progenitors.[94] BMP4 levels are increased by FGF10-FGR2b and WNT/β-catenin signaling in distal buds.[93] The availability of BMP4 protein in these buds is controlled by Cathepsin H (Ctsh), a cysteine protease induced by FGFR2 in the embryonic lung. Inhibiting CTSH activity markedly accumulates BMP4 protein, interfering with branching morphogenesis.[95] Additional regulators of BMP4 during P-D patterning include histone deacetylases (Hdac1/2)[96] and HOX5-WNT2/2b.[97]

The mechanisms by which distal epithelial buds (SOX9+ ID2+) give rise to epithelial progenitors of the airway compartment (SOX2+) are still poorly understood. There is evidence that this process is under the control of the Hippo-YAP pathway. The transcriptional co-regulator Yap (Yes-associated protein) is a key modulator of cell fate and proliferation during development. YAP transcriptional activity is dependent on its phosphorylation status, determined by the Hippo serine/threonine kinases (such as MST1/2, LATS1/2), which regulate YAP subcellular localization. Unphosphorylated YAP is maintained in the nucleus, where it activates downstream targets through binding to TEA-domain (Tead) family transcription factors.[98] In the developing lung epithelium, nuclear YAP has been reported predominantly in SOX9+ distal progenitors while cytoplasmic phospho-YAP was shown in SOX2+ proximal progenitors. Disruption of Yap in epithelial progenitors at the onset of lung development results in severely impaired branching morphogenesis with reduction in the SOX2+ airway progenitors and expansion in the SOX9+ distal compartment.[99] Another study of compartment-specific YAP functions reveals that nuclear YAP in distal progenitors is essential for lung branching, while cytoplasmic YAP is required for proper differentiation.[100] These studies suggest that YAP controls the specification of airway progenitor cells at the transition zone between the SOX9-SOX2 domains, presumably by rendering epithelial cells competent to respond to proximalizing signals.[99,101] Disruption of Lats1/2 using similar genetic strategy also results in dramatic impairment of branching morphogenesis, but both SOX9 and SOX2 compartments are equally affected.[102]

miRNAs also play a significant role in lung P-D patterning. For example, the miR-17-92 cluster is expressed during early lung development; gain of function selectively in the developing lung epithelium of transgenic mice results in increased cell proliferation.[103] Conversely, miR-17-92 cluster knockout mice have hypoplastic lungs.[104] In an independent study, miR-17 family members were shown to modulate FGF10-FGFR2b downstream signaling by targeting STAT3 and MAPK14.[105] miR-302/367, a direct target of GATA6, coordinates the balance between proliferation and differentiation of lung epithelium by directly regulating the expression of Rbl2 and Cdkn1a. Overexpression of miR-302/367 leads to expansion of both proximal and distal lung progenitors and regulates epithelial apical-basal polarity.[106]

FORMATION OF THE VASCULAR AND OTHER MESENCHYMAL COMPONENTS OF THE LUNG

Besides playing a crucial role in epithelial development, the lung mesenchyme gives rises to the vascular, cartilage, and other stromal components of the lung. Lineage tracing studies reveal that a multipotent cardiopulmonary progenitor population marked by Wnt2, Gli1, and Isl1 generates the mesodermal progenitors that give rise to the cardiac inflow tract and the lung vasculature, except for the distal alveolar capillary endothelium, which is derived from a VE-CADHERIN+ population.[107] In turn, expansion and differentiation of mesenchymal progenitors into these different components require diffusible signals from the epithelial and mesothelial (pleural) layers. Pulmonary veins arise from cardiac progenitors migrating from the neighbor atria. VEGF signaling plays a major role in vascular development by promoting endothelial cell differentiation[108] (Fig. 4-3). VEGFA is found predominantly in the distal lung epithelium but also in the mesenchyme at early stages and signals through VEGFR2 (Flk1) and VEGFR1 (Flt1) in the mesenchyme.[109–111] Among the several VEGF isoforms, VEGF164 is the most active in the lung.[111] Development of lymphatic vessels is still poorly understood. Studies in mice show that VEGF-C and VEGF-D acting through their receptor VEGFR-3 promote lymphangiogenesis.[112,113] Vegfr-3 null mice fail to proper develop lymphatic vessels.[114]

Smooth muscle (SM) is an integral component of vascular and airway epithelium of the lung (Fig. 4-3). Vascular SM develops by contribution from mesenchymal precursors through signals derived from the epithelium but also from pleural cells migrating to the vascular structures during blood vessel assembly.[115] Shh signaling from the anterior foregut endoderm affects proliferation and differentiation of lung mesenchymal cells, and it is required for SM development.[116,117] A signaling cascade involving SHH, miR-206, and BDNF (brain-derived nerve growth factor) coordinates innervation and formation of the airway SM layer.[118] Moreover, miR-29, abundantly expressed in SM cells associated with distal vessel walls during postnatal lung development, suppresses the expression of Klf4 and extracellular components and promotes the maturation of vessel walls.[119] WNT7b, acting through its receptors FZD1 and FZD10 and its co-receptor LRP5 (low-density lipoprotein receptor-related protein 5), is an important epithelial signal required for vascular SM development and the integrity of blood vessels.[120] Wnt7b null mice show hemorrhagic lungs resulting from rupture of the blood vessels due to SM structural defects.[121] GPR177, which regulates WNT secretion, is essential for vascular SM development and maintenance.[122]

Assembly of the pulmonary arterial wall occurs through controlled migration of SM cells from the inner to the outer layers in a process mediated mostly by PDGFB.[123] In addition, vascular SM formation depends on BMP and NOTCH signaling.[124,125] Bmp4 and Bmpr2 are expressed in SM precursors, and disruption of BMP signaling is associated with increased SM cell proliferation. This phenotype is reminiscent of the excessive SM growth reported in pulmonary hypertension patients with mutations in the Bmpr2 gene.[126–128] Disruption of canonical NOTCH signaling interferes with specification of arterial SM cells.[125] NOTCH3 dysregulation is associated with structural changes in the pulmonary artery postnatally and has been implicated in the pathogenesis of adult pulmonary hypertension.[129,130] The importance of having a precisely matched airway–vascular development is well illustrated by the role of Foxm1, a transcription factor expressed in the lung mesenchyme. Foxm1 null mice show pulmonary hemorrhage and perinatal death due to misalignment of epithelial and vascular structures.[131] This phenotype closely reminds the abnormalities seen in human congenital alveolar dysplasia.

During development, airway SM is responsible for phasic contractility of airways and growth factor production, contributing to maintain normal lung growth. Previous studies have ascribed a role for airway peristalsis in epithelial branching.[132,133] However, a more recent analysis of a myocardin (Myocd) conditional mouse model in which airway SM differentiation was disrupted showed no branching defect.[134] Airway SM originates from mesenchymal cells of the developing lung when the initial airway starts to branch, preceding the appearance of the lung vascular SM. A lineage tracing study using Fgf10-CreERT2 suggests that FGF10+ cells at the early pseudoglandular stage serve as the progenitors for both myogenic and adipogenic lineages, and later no longer give rise to SM cells.[135] The FGF10+ mesenchymal progenitors, initially surrounding the distal buds, expand and migrate proximally to enwrap the proximal airways.[136,137] This myogenic program is likely to be triggered by high levels of BMP4 and SHH present at the bud tips[51,91] (Fig. 4-3). Canonical WNT signaling is required for the expansion of the SM progenitors in developing airways.[138] Proper differentiation of the airway SM requires input from pathways, including FGF and TGF-βR, as well as physical stretch transduced by tension-induced proteins such as TIP1.[139,140] FGF9-FGFR1/2 signaling suppresses airway SM differentiation through inhibition of Myocd expression.[141,142]

Analysis of models in vivo and in vitro provide evidence that endogenous RA is active in the mesenchyme associated with distal buds of branching airways. At these sites RA transiently inhibits SM differentiation, preventing precocious and excessive formation of SM. These sites of RA activation coincide with sites where SM differentiation signals, such as TGF-β and MYOCD, are dynamically active.[143] RA downregulates TGF-β signaling in the developing lung. Maternal vitamin A deficiency results in aberrantly increased and ectopic formation of SM in fetal airways. The effect can be similarly reproduced by disrupting RA signaling in lung explant cultures. This is relevant since vitamin A deficiency in utero, even for a short period, can have deleterious consequences during postnatal life. Indeed, administration of a vitamin A–deficient diet to pregnant mice for only 4–5 days with subsequent normal levels to adulthood leads to offspring with markedly thick airway SM layer and airway hyperresponsiveness.[143] Interestingly, the effect of RA deficiency in the SM program is not seen in blood vessels, suggesting different molecular regulation of SM differentiation within the same organ.

Cartilage rings present in trachea and proximal airways develop from the precursors in ventral mesenchyme. Proper formation and patterning of cartilage primordia require signaling by WNT-NOTUM (Notum being a target of WNT/β-CATENIN pathway that attenuates WNT signaling), retinoic acid (particularly RARγ-mediated), FOXF1, and SHH, among others.[144–147] Airway SM and cartilage develop coordinately and complementarily: genetic inactivation of Srf leads to loss of airway SM and increase in cartilage, while inactivation of Sox9 leads to loss of cartilage and increase in SM.[148]

AIRWAY DIFFERENTIATION

As the epithelial tubules form and branch, they initiate a program of cell fate choice and differentiation that ultimately gives rise to the various airway epithelial cell types. Airway epithelial cells are collectively marked by expression of Sox2, which extends from the developing trachea and branching tubules to the stalks of the growing buds[149] (Fig. 4-4). By the middle of the pseudoglandular period (~E12.5–E14.5 in mice) airway lineages progressively start to be specified in secretory, multiciliated, and neuroendocrine precursors, as seen by expression of Scgb3a2, Foxj1, and Ascl1, respectively. These phenotypes arise from a process of cell fate selection in the SOX2+ progenitors crucially dependent on cell–cell interactions mediated by NOTCH signaling. Notch receptors (Notch 1, 2, 3) and ligands (Jag1, Jag2, Dll1, Dll4) are expressed in the developing lung. Cells in which NOTCH is activated assume a secretory fate; otherwise they commit to a multiciliated or neuroendocrine fate.[125,150–152]

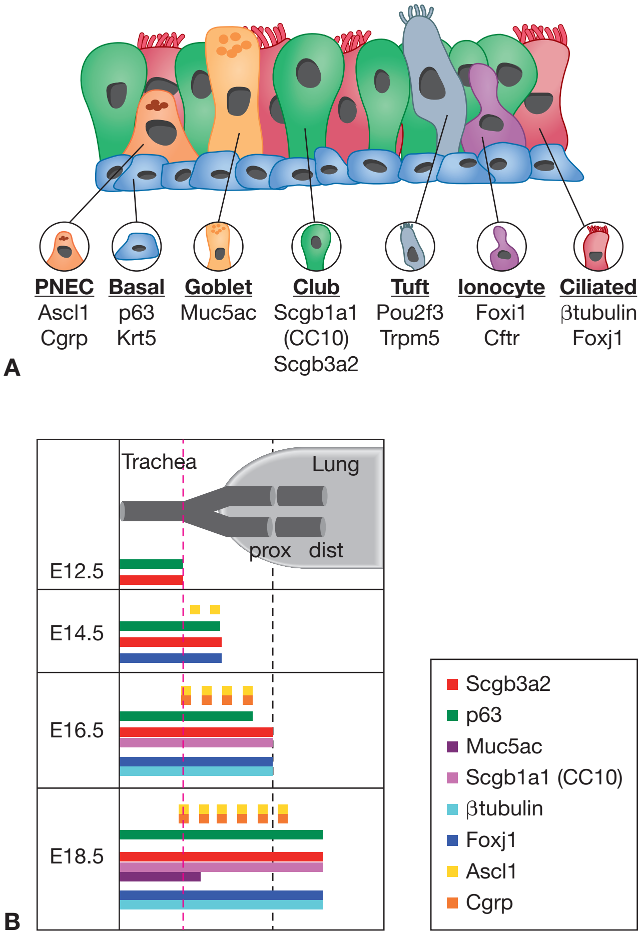

Figure 4-4 Epithelial differentiation in conducting airways. **A.** Cell types and markers associated with or required for the differentiation of specific cells in adult airways. **B.** Time course of appearance of gene markers associated with different cell lineages in trachea, and proximal and distal airways of the developing mouse lung.

Different Notch receptors and ligands play distinct roles in airway development.[153,154] NOTCH3 is required at early stage for the generation of parabasal cells in extrapulmonary airways, which then activate NOTCH1 or 2 for ciliated-secretory fate selection.[155] JAG ligands regulate the balance of basal, ciliated, and secretory cells, while DELTA ligands restrict the NEB microenvironment.[154] Downregulation of NOTCH pathway components has been identified in patients with chronic obstructive pulmonary disease (COPD).[156]

Formation of multiciliated cells in the airways depends on the activity of MULTICILIN and its transcriptional effector E2F4. In the absence of these regulators, airways have no multiciliated cells.[157] E2F4 is essential to induce a transcriptional program of centriole biogenesis that allows large-scale centriole multiplication from which cilia emerge. Interestingly, once this program is initiated, E2F4 undergoes nucleocytoplasmic shuttling and acts as an apical organizing center for assembly of deuterosomes to ultimately form centrioles.[158] Apical docking of centrioles to initiate multiciliogenesis depends on FOXJ1. Foxj1 null mice are unable to form multiciliated cells.[159] miR-449 has been shown to promote the differentiation of multiciliated cells by targeting Notch1 and Dll1 in human airway epithelial cells.[160]

Secretory cell precursors are identified initially by SCGB3A2+ cells at around E12.5 and subsequently acquire additional markers, such as CC10 (Scgb1a1),[161,162] as they differentiate into Club cells. Lineage tracing using CC10-CreERT2 provides evidence that Club cells are the progenitor/stem cells in intrapulmonary airways. They are shown to self-renew and generate multiciliated cells during development and homeostasis and in injury repair.[163] However, this population is heterogeneous. For example, those associated with neuroendocrine cells express a few distinct genes and are considered as immature (or variant) Club cells in the adult lung, since they can survive exposure to an environmental agent (naphthalene) and repopulate the damaged epithelium.[164–166]

Mucin-secreting (MUC5ac+) goblet cells are relatively rare in developing mouse airways, occurring mostly postnatally in trachea and proximal airways. Their abundance is increased in adult mice during exposure to environmental agents or infection.[167] By contrast in humans, goblet cells are seen throughout the airway epithelium. NOTCH signaling is critical for the lineage balance of different cell types in the airways.[150] Disruption of NOTCH signaling in mice results in loss of secretory (Club) cells and airways overpopulated by multiciliated and NE cells.[125,150,153,168] Conversely, constitutive activation of NOTCH in the embryonic lung epithelium leads to a decrease in number of multiciliated cells and increase in secretory goblet cells.[152] Goblet cell differentiation is also controlled by transcription factors, such as Spdef (SAM-pointed domain-containing Ets transcription factor) and Foxa2.[169–171]

Neuroendocrine cells are relatively rare, and their lineage marker Ascl1 is first expressed in developing airways around E12.5 in scattered airway cells in proximal regions. There is evidence that these NE progenitors assemble into clusters (bodies, thus the term *NEB*) at the branchpoints of intrapulmonary airways through a "slithering" migratory activity.[172] The ability to cluster is dependent on ROBO-SLIT pathway. NEBs are important in the regulation of neuropeptide production and immune response to environmental agents.[173] Mice deficient in Ascl1 do not form NE cells or NEB, and they exhibit substantially impaired immune response and goblet-cell hyperplasia, suggesting essential roles of NE cells as sensory and neuroimmunologic modulators in airways.[174,175] Within NEB, rare NE cells serve as reserve stem cells, which are activated by injury and reprogrammed to other airway lineages surrounding the NEB for regeneration. These even rarer stem NE cells might serve as tumor initiating cells for small cell lung cancer (SCLC).[176] NE cells recently have been discovered in mouse trachea, and although rare, they are heterogeneous in expression of neuropeptides and TUBB3.[177,178] It remains unclear how basal cells generate tracheal NE cells as well as how intrapulmonary NE cells are specified during development. Addressing these questions will probably shed light on the pathogenesis of pulmonary diseases associated with NE hyperplasia, like neuroendocrine hyperplasia in infancy (NEHI) and sudden infant death syndrome (SIDS).

Basal cells are considered the principal source of almost all the epithelial lineages in extrapulmonary airways of the adult mouse lung. Lineage studies using Krt5-CreERT2 and p63-CreERT2 suggest that prenatal basal cells, specified at E13.5, function as progenitors to both ciliated and secretory cells during development, similar to their postnatal counterparts.[79,179] p63 null mice do not form basal cells in the lung or other tissues to undergo pseudostratification in the tracheal epithelium or stratification in other tissues.[30,180–183]

Recent single-cell RNA sequencing studies chart the comprehensive epithelial landscape in adult airways and reveal rare cell types, including Tuft cells, ionocytes, and hillock cells. Although constituting less than 1% of total epithelial population, these rare cell types play important roles in immunologic, neuronal, and chemosensory functions.[177,184–186] These cells are also associated with pulmonary diseases: ectopic Tuft cells were identified in H1N1 influenza virus–induced dysplastic epithelium and may contribute to eosinophil recruitment and mucous hyperplasia after severe lung injury.[187] Ionocytes express Cftr transcripts and may contribute to the pathogenesis of cystic fibrosis. Hillock cells exhibit higher turnover rate and express squamous cell markers, potentially related to metaplastic changes in the airway epithelium.[177,183] Notably, the developmental origin of these cell types remains so far elusive and await further exploration.

FORMATION OF THE GAS EXCHANGE REGION OF THE LUNG

Once branching morphogenesis is completed, distal epithelial buds undergo sacculation. During this morphogenetic process, the lumen of epithelial tubules enlarges at their distal ends to form primitive saccules and AT1 and AT2 cells differentiate. During formation of AT1 cells the progenitors undergo flattening and folding[188] to cover the large area occupied by these saccules. The mesenchyme becomes thinner, and the epithelium comes into intimate contact with the capillary network of the primitive saccules to form the primitive alveolar-capillary barrier.[189] AT2 cells remain cuboidal and produce surfactant to reduce surface tension and facilitate breathing postnatally.

Single-cell RNA sequencing and lineage tracing analyses have suggested that AT1 and AT2 cells originate from a common distal bipotent progenitors present at the onset of sacculation.[190] However, a more recent study shows that AT1 and AT2 lineages are already specified as early as E13.5 when airways are still actively branching.[191] The balance of AT1 versus AT2 lineages is tightly controlled. One key regulator of this balance is the Hippo/YAP/TAZ pathway. Notably, during sacculation nuclear Yap signaling is activated in the progenitors differentiating selectively into AT1 cells, while Yap is kept largely cytoplasmic in those differentiating into AT2 cells. Yap knockout in the lung epithelium prevents AT1 cells from forming. Conversely, constitutive expression of nuclear Yap transgene increases the AT1 number.[100,102] At late gestation fetal breathing-induced mechanical forces contribute to promote flattening of progenitors differentiating into AT1 cells, while FGFR2-ERK activation in differentiating AT2 cells by local mesenchymal FGF10 prevents flattening, maintaining their cuboidal shape[192] (Fig. 4-5). Interestingly, AT1 cells are found to be highly plastic and can give rise to AT2 cells during repair after hyperoxic injury during the neonatal period.[193] However, this mechanism is not efficient as seen in the adult lung when both AT1 and AT2 can function as progenitor cells.[189,194–197,199] Whether this developmental fate choice is due to plasticity of AT1/AT2 cells or bipotential progenitors remains to be investigated further. Defects in sacculation have been reported in several gene knockout mouse mutants. These include mutants

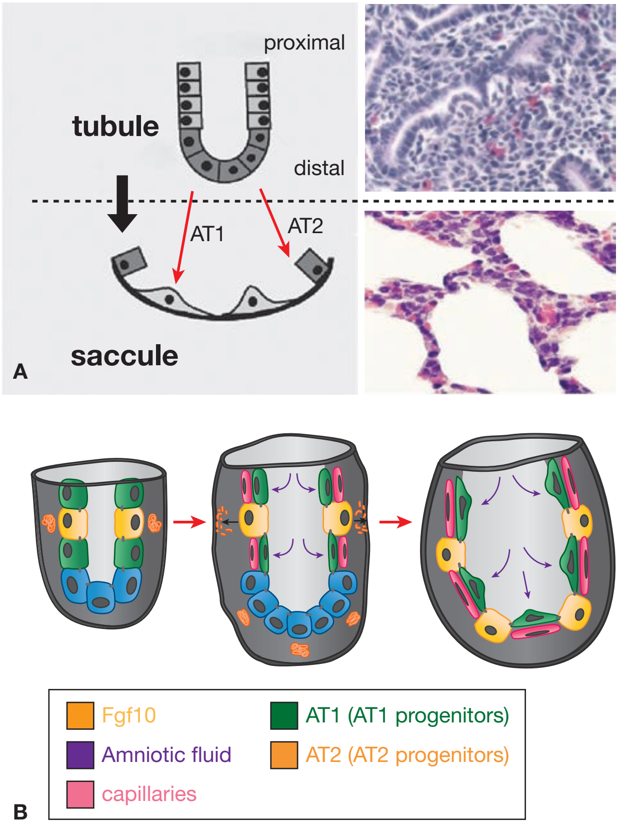

Figure 4-5 Sacculation. **A.** Distal epithelial tubules expand their lumens and form primitive saccules lined by alveolar type I and type II cells. **B.** During transition from canalicular to saccular stage, distal epithelial progenitors start to protrude toward the mesenchyme through local activation of Fgf10-Fgfr2 signaling and later become AT2 cells. Non-protruded cells are flattened by increased intraluminal pressure with inhaled amniotic fluid, and differentiate into AT1 cells.[192]

for T1α,[198] Nfib (nuclear factor I/B),[199] Erk3 (extracellular signal-regulated kinase 3), and Foxm1.[200]

By late gestation in humans or postnatally in mice the primitive saccules subdivide into smaller units to form the mature alveoli, which greatly increases the surface area for gas exchange (Fig. 4-5). Development of the mature alveoli (alveologenesis or alveolarization) involves formation of secondary septa, which greatly increases the surface area for gas exchange (Fig. 4-5). This process (alveologenesis or alveolarization) has been thought to involve formation of secondary septa from the saccule wall, which protrude into the lumen pushed by myofibroblasts. Interestingly, recent 3D reconstruction analysis shows a continuous network of myofibroblasts and elastin forming "cables" underlining the nascent septae. This suggests a very different mechanism in which these "cables" act as anchor points that form the alveolar ridges as the septal walls are pushed out by airway pressure from breathing movements, resulting in subdivisions of the original saccule (mature alveoli).[201]

Alveolar formation requires tight control of elastin levels by signals such as PDGF, FGFR3/4, and MFAP5 (Fig. 4-6).[202–204] This process is also controlled by many other signals, including VEGF-FLT1,[205] FOXN4,[206] VEGFA,[188] UPR (unfolded protein response) pathway,[207] HOX5,[208] and IGF1R.[209] Disruption of these signals can lead to immature lungs with decreased alveolar septation.

FINAL REMARKS

A wealth of information has been generated over the past decades on how growth factors, transcription factors, and matrix components influence lung development. Many of these studies suggest that alterations in developmental pathways reported in animal models are relevant to understand the pathogenesis of human lung conditions. There is also increasing evidence that developmental regulators are recruited in different contexts to mediate normal and aberrant injury-repair responses in the adult lung. Further understanding of these issues will be invaluable in discovery of different therapeutic targets and in the new field of lung regenerative medicine.

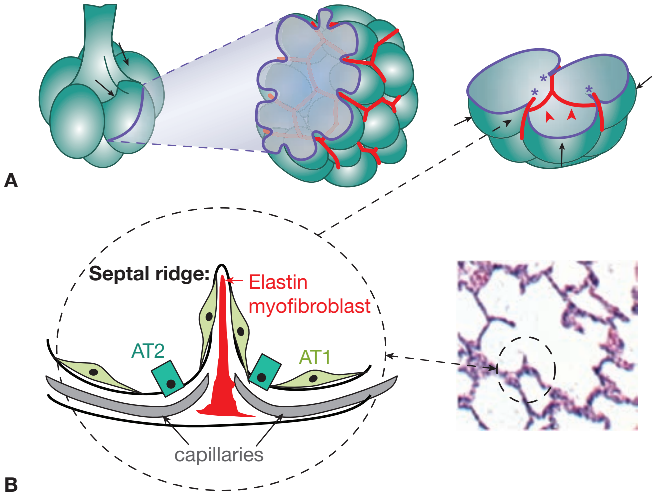

Figure 4-6 Alveolar formation. Diagram from 3D reconstruction of distal lung undergoing alveolarization. Myofibroblasts and elastin (in red) form "cables" that serve as anchor points (septal ridges) while the septal walls are pushed away by airway pressure from breathing movements **(A)** resulting in subdivision of the saccules in multiple alveoli **(B)**.[201]

CHAPTER 5

Pulmonary Surfactant and Disorders of Surfactant Homeostasis

Jeffrey A. Whitsett
James P. Bridges
Timothy E. Weaver

INTRODUCTION

Pulmonary surfactant is a complex mixture of phospholipids and proteins that creates a unique interface separating alveolar gas and liquids at the alveolar cell surface, reducing surface tension, and maintaining lung volumes at end expiration. Reduction of the surface tension at the air-liquid interface is a requirement for respiratory function following birth and throughout life. Deficiency of pulmonary surfactant causes respiratory failure in premature infants, or infantile respiratory distress syndrome (IRDS). The adequacy of pulmonary surfactant is maintained by unique and highly regulated systems mediating the synthesis, secretion, reutilization, and catabolism of surfactant. Loss of pulmonary surfactant later in life occurs in the adult respiratory distress syndrome (ARDS), a significant cause of morbidity and mortality following infection, shock, or trauma. Mutations in genes regulating surfactant homeostasis, including *SFTPA*, *SFTPB*, *SFTPC*, *ABCA3*, *NKX2-1*, and *CSF2RA/B* cause acute and/or chronic lung disease in newborn infants, children, and adults. Disorders of GM-CSF signaling inhibit surfactant lipid and protein catabolism by alveolar macrophages causing pulmonary alveolar proteinosis (PAP). This chapter reviews the biology of the surfactant system and its implications for the pathogenesis, diagnosis, and treatment of respiratory disease in premature infants and adults. Reviews of these topics are suggested.[1–7]

PHYSICAL FORCES AT THE AIR-LIQUID INTERFACE

In 1929, Van Neergard recognized the critical role of surface tension as a “retractile force” in the lung, observing the markedly increased pressures required to inflate the air- versus water-filled lung. Avery and Mead associated the lack of a lipid-rich material in the lungs of infants dying from IRDS with alveolar collapse and respiratory failure.[8] In the absence of pulmonary surfactant, molecular forces at the air-liquid interface create a region of high surface tension because intermolecular forces between water molecules are unopposed at the air-liquid interface, and an area of high retractile force at the surface is created. Forces of 70 dyn/cm^2 are generated at the air-water interface; if unopposed in the alveolus, such forces lead to alveolar collapse and respiratory failure. A surface film composed of multilayered sheets of phospholipids creates a distinct phase separating air and liquid, reducing surface tension to nearly zero and maintaining residual lung volume at end expiration. Complex interactions between surfactant phospholipids and proteins are required to maintain the surfactant film throughout life. Pulmonary surfactant lipids and proteins are synthesized and secreted by alveolar type 2 (AT2) cells into the alveoli, where they form multilayered lipid rich films that reduce surface tension to maintain ventilation (Figs. 5-1 and 5-2).

COMPOSITION OF PULMONARY SURFACTANT

Pulmonary surfactant isolated by lung lavage consists of highly heterogeneous forms of phospholipid-protein aggregates of distinct sizes, structural characteristics, and composition. Tubular myelin is the most abundant form of alveolar phospholipid and consists of large, relatively dense aggregates (termed *large aggregate surfactant*) composed of phospholipids and surfactant proteins. Tubular myelin is a highly organized form of surfactant phospholipid, forming square tubular arrays. Tubular myelin represents an extracellular pool of surfactant lipids that rapidly moves to the air-liquid interface and re-organizes to form multilayered sheets that reduce surface tension in the alveolus (Fig. 5-2). Large lamellated structures, with lipid composition similar to that of tubular myelin, are seen within the alveolus and likely represent newly secreted lamellar bodies that unravel to form tubular myelin in the alveoli. The phospholipid composition of lamellar bodies, the intracellular storage form of surfactant, tubular myelin, and lamellated forms present in the alveolus are virtually identical. Smaller, less dense particles (small aggregate surfactant) also are present within the alveolar space, representing remnants or catabolic forms of surfactant that have relatively poor surface activity. Small aggregate surfactant is destined for uptake, reutilization, or catabolism by AT2 cells and catabolism by alveolar macrophages.[2,3]

■ Surfactant Phospholipids and Proteins

The composition of surfactant lipids is similar in all of the structural forms of surfactant isolated from mammalian lungs, with phospholipids generally representing 80% to 90% of the mass of

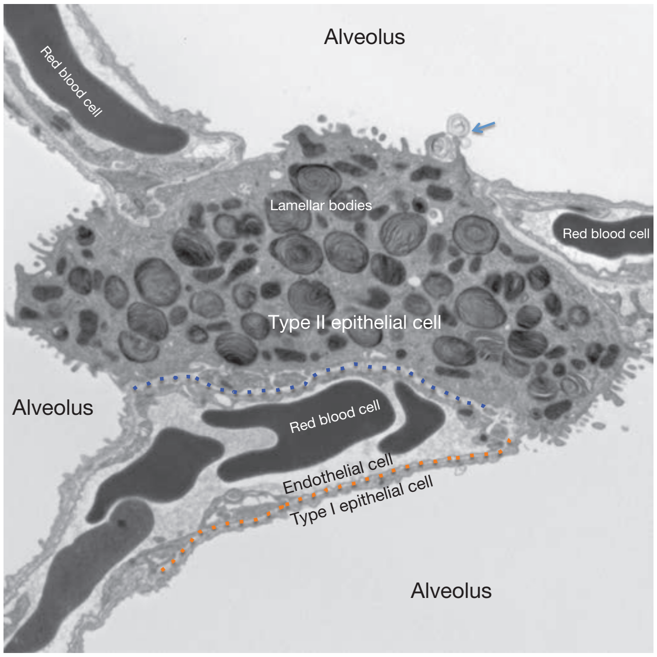

Figure 5-1 Pulmonary alveolar ultrastructure. The air-blood barrier comprises the capillary endothelium (above the dotted orange line) and the closely apposed type I epithelial cell (below the dotted orange line). The dotted blue line delineates the interstitial space between endothelial cells and AT2 cells with their specialized secretory lipid organelles (lamellar bodies). AT2 cells form tight junctions with type I cells and serve as alveolar progenitor cells. Surfactant lipids and proteins are secreted as lamellar membranes (arrow) into the alveolar space forming tubular myelin and lipid membrane multilayers that reduce surface tension, preventing alveolar collapse.

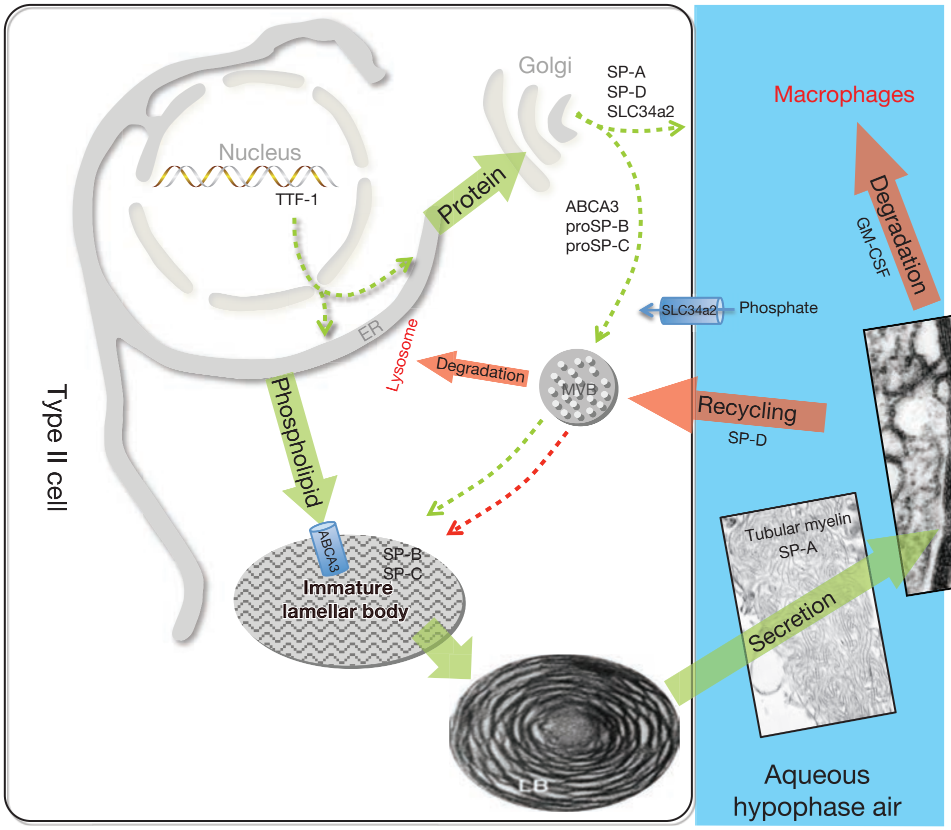

Figure 5-2 Surfactant metabolism. Newly translated surfactant proteins (proSP-B and proSP-C) and lamellar body (ABCA3) proteins traffic from the endoplasmic reticulum (ER) to the Golgi and subsequently to the multivesicular body (MVB). Fusion of the MVB with the lamellar body (LB) is accompanied by proteolytic processing of SP-B and SP-C proproteins to their mature peptides. Surfactant phospholipids (DPPC, PG) are likely transported directly from the ER to the LB by lipid transfer proteins. The contents of the LB are secreted into the alveolar space where they interact with SP-A to form tubular myelin and, ultimately, a phospholipid-rich film (surfactant) at the air-liquid interface. Alveolar surfactant lipids and proteins are cleared through a GM-CSF-dependent pathway that regulates alveolar macrophage differentiation and function. Surfactant remnants are also taken up by the AT2 cell and recycled to the LB, via the MVB, for resecretion, while a portion is degraded in lysosomes. SP-D plays an important role in regulating alveolar surfactant pool size likely by enhancing its reuptake by AT2 cells. The MVB serves to integrate surfactant synthesis, secretion, recycling, and degradation pathways in the AT2 cell. TTF-1 is a transcription factor critical for differentiation of AT2 cells and regulation of expression of Abca3, Slc34a2, and the surfactant proteins. Synthetic pathways are shown in green and catabolic pathways are shown in red.

pulmonary surfactant.[3] In the adult lung, phosphatidylcholine (PC) and phosphatidylglycerol (PG) are the most abundant phospholipids, representing approximately 70% to 80% and 5% to 10%, respectively, of the lipid mass. Dipalmitoyl phosphatidylcholine (DPPC) is the most abundant species of PC. Lesser amounts of phosphatidylserine, phosphatidylethanolamine, sphingomyelin, neutral lipids (mostly cholesterol), and glycolipids also are present in surfactant. The fetal lung content of surfactant phospholipids increases markedly with advancing gestation, regulated by a complex signaling and transcriptional network that controls AT2 cell differentiation, lipid synthesis, and surfactant protein gene expression. Lamellar bodies are secreted into the fetal amniotic fluid. PC, lamellar body counts, DPPC content, and increased lecithin (PC) to sphingomyelin (L/S) ratio, correlate with postnatal respiratory function. These tests are used to predict pulmonary maturity prior to the birth of preterm infants. Lung maturation and synthesis of surfactant components are induced by maternal administration of glucocorticoids, used clinically to prevent respiratory distress prior to premature birth.[9] Proteins represent approximately 5% to 15% of the mass of pulmonary surfactant and include serum proteins and proteins that are synthesized and secreted by AT2 cells. In addition to its specific interaction with SP-B, the anionic phospholipid PG may also play an important role in innate defense. PG constitutes 10 mole% of surfactant lipid, with palmitoyl-oleoyl-PG (PoPG) being the most common species in human surfactant. PoPG specifically suppresses LPS-induced inflammatory responses and prevents infection of epithelial cells by binding RSV or influenza A virus (IAV).[10] Phosphatidylinositol (PI), a minor anionic phospholipid species in the pulmonary surfactant, also inhibits RSV and IAV infection in mice.[11,12] Thus, the unique enrichment of PoPG and PI in the distal airspaces may be important components of host defense against inhaled pathogens. Four surfactant proteins (SP), SP-A, SP-B, SP-C, and SP-D, are produced by respiratory epithelial cells, each playing specific roles in surfactant homeostasis and innate host defense.[2,3,13,14]

Surfactant is uniquely enriched in disaturated DPPC. The saturated C16 acyl chains pack densely at an air-liquid interface, reducing tension at the surface. However, dense and stable packing of DPPC occurs at a phase transition of 41°C, far above physiologic temperatures. Thus, at 37°C, pure DPPC maintains a semicrystalline or gel phase that is incapable of moving rapidly with the expansion and compression of the alveoli during the respiratory cycle. The capability of DPPC pulmonary surfactant to move rapidly to the alveolar interface at 37°C and to maintain low surface tension during dynamic compression is conferred by the surfactant-associated proteins SP-B and SP-C. Phosphatidylcholine synthesis in the lung is controlled by genes encoding choline phosphate cytidyltransferase

(PCYTLA and CHKA), which are required for surfactant lipid synthesis and lung function at birth. A transcriptional network, controlled by sterol-response element binding proteins (SREB), regulates a number of key enzymes involved in phospholipid synthesis by AT2 cells.[15] DPPC is synthesized in AT2 cells via both a de novo pathway and remodeling of lysoPC. The enzyme LPCAT1 (lysoPC acyltransferase) mediates reacylation during surfactant lipid biosynthesis, enhancing the abundance of saturated PC.[16,17] Surfactant lipids, synthesized in the endoplasmic reticulum (ER), are transferred via a Golgi-independent pathway to lamellar bodies, the major intracellular storage site of surfactant (Fig. 5-2). Transfer of lipids in AT2 cells occurs via nonvesicular transport, and uptake into lamellar bodies requires the ABCA3 transporter, which selectively transports PC and PG. In contrast, surfactant proteins SP-B and SP-C traffic from the ER to the Golgi and subsequently to multivesicular bodies and lamellar bodies completing proteolytic processing of the proproteins. Ultimately, multivesicular bodies are incorporated into lamellar bodies with surfactant lipids prior to secretion into the alveoli by AT2 cells.[3]

Structure and Function of Surfactant Proteins

Four distinct surfactant associated proteins have been isolated from surfactant obtained by lung lavage. Their cDNAs, genes, and structures have been identified and are well characterized (Table 5-1).[13,14] The surfactant proteins are expressed in a relatively lung epithelial cell–selective manner and are secreted into the airspaces, where they influence the structure, metabolism, and function of surfactant. Two classes of proteins have been distinguished on the basis of their structures. SP-A and SP-D are relatively abundant, hydrophilic, structurally related proteins and are members of the calcium-dependent lectin family of proteins that have similar amino-terminal collagenous and C-terminal lectin domains.[18] SP-A and SP-D have few "surfactant"-like qualities but are able to bind complex carbohydrates, lipids, and glycolipids, including those on the surface of cells, bacteria, viruses, fungi, and other lung pathogens. SP-A and SP-D influence the structural forms and metabolism of surfactant lipids in the alveolus. They act as opsonins, activate alveolar macrophages, and play important roles in innate host defense in the lung. In contrast, SP-B and SP-C are small, hydrophobic proteins that play critical roles in enhancing the rate of spreading and stability of surfactant phospholipids needed to optimally reduce surface tension.[14] SP-B and SP-C are the sole protein components of the animal-derived surfactant replacement preparations used for the treatment of IRDS at present.[14] Mutations in the genes encoding SP-A, SP-B, and SP-C cause diffuse pulmonary disease affecting infants and older individuals.[19,20]

Surfactant Protein B (SP-B)

Surfactant protein SP-B is a hydrophobic, amphipathic 8.8-kDa protein produced from a single gene (*SFTPB*, OMIM 178640) located on human chromosome 2 (Table 5-1). The SP-B mRNA is expressed in non-ciliated bronchiolar cells and AT2 cells and is translated to produce a 40- to 42-kDa precursor that is proteolytically processed in the secretory pathway of AT2 cells to form the active 79-amino-acid peptide found in alveolar surfactant. In combination with lipids, SP-B can reconstitute most of the surface activity of natural lung surfactant. SP-B contains two regions, (Trp$_9$-Pro$_{23}$) and (Ile$_{56}$-Pro$_{67}$), predicted to form amphipathic α-helices that interact with the surface of lipid films. Almost 50% of the protein is in an α-helical conformation; the amphipathic domains of SP-B interact with surfactant lipids, and PG in particular, to promote lipid incorporation into and stabilization of the surface film. SP-B contains three intramolecular disulfide bonds that confine the amphipathic helices of SP-B in an antiparallel configuration. The SP-B monomer is assembled into a higher order hydrophobic ring, consisting of 6 covalently linked dimers, that is anchored to the surface of secreted surfactant membranes via the helical domains;[21] stacking of SP-B rings connects adjacent surfactant membranes to form a multilayer reservoir of phospholipids in the airspaces.[22] The membrane-perturbing properties of SP-B promote reorganization of surfactant membranes and facilitate transfer of phospholipids to the alveolar air-liquid surface film.

ProSP-B is synthesized in the endoplasmic reticulum and proteolytically processed in multivesicular and lamellar bodies by cathepsins and other intracellular proteases. The active SP-B peptide is packaged with SP-C and surfactant lipids in lamellar bodies prior to secretion into the alveolus. In the alveoli, the positively charged amino acid residues of SP-B selectively interact with the negatively charged phospholipid DPPG. In a mixed DPPC/DPPG monolayer, SP-B is believed to purify the DPPC monolayer by removal of DPPG. SP-B increases order in the lipid head groups with little effect on order in the lipid membrane interior. The ability to order

TABLE 5-1 Genetic Causes of Disorders of Surfactant Homeostasis

Genes/Locus	Functions	Inheritance	Presentation	Age at Presentation
ABCA3 16p13.3	Lipid transport, surfactant packaging/function	AR	RDS ILD	Newborns, children
SFTPB 2p12	Surfactant packaging/function	AR	RDS	Newborns
SFTPC 8p21	Surfactant function	AD	ILD > RDS	Infants, children, adults
SFTPA 10q22.2	Tubular myelin, host defense	AD	ILD/lung cancer	Adults
TTF-1 14q13	Lung, thyroid, CN morphogenesis, surfactant regulation	AR haploinsufficiency	Thyroid/lung/CNS malformations, ILD	Newborns, infants
GMCSFRα 22.32	Alveolar macrophage function	AR	PAP	Children
GM-CSF 15q31	Alveolar macrophage function	Autoimmune	PAP	Adults

Abbreviations: RDS, respiratory distress syndrome; ILD, interstitial lung disease; PAP, pulmonary alveolar proteinosis; AR, autosomal recessive; AD, autosomal dominant.

the lipid head group region is located in the amino- and carboxy-terminal regions of SP-B (1-20) and (53-78), which contain the predicted amphipathic helices. Synthetic peptides that contain these two regions have surface tension–lowering activity similar to that of native SP-B, and peptide mimics have been developed for therapy of respiratory distress in infants. SP-B enhances the insertion (fusion) of phospholipid vesicles into a preformed DPPC/DPPG monolayer, particularly in the presence of divalent cations. SP-B causes lipids in solution to form discoid particles often appearing as stacks or sheets. Together with SP-A, lipids, and Ca^{2+}, SP-B reconstitutes the characteristic ultrastructural features of tubular myelin, producing multilamellar aggregates and square lattice configurations. Recent findings support a potential role for SP-B in the secretion of lamellar bodies from AT2 cells, mediated in part by enhancing Ca^{2+}-dependent purinoreceptor signaling and exocytosis.[23]

■ SP-B Is Required for Survival After Birth

Mutations in the gene encoding SP-B (*SFTPB*, OMIM 265120) cause acute respiratory failure at birth related to surfactant dysfunction.[24,25] Similarly, deletion of *Sftpb* in the developing lung or its conditional deletion in adult mice causes acute respiratory distress associated with alveolar capillary leak and surfactant deficiency.[26] Pathologic findings of patients with lung disease related to *SFTPB* mutations are similar to those in mice in which the *Sftpb* gene is deleted.[26,27] SP-B deficiency is associated with failure to form lamellar bodies, accumulation of abnormal multivesicular bodies within the AT2 cells, and failure to form tubular myelin or functional surfactant films after secretion into the alveoli.

■ Hereditary SP-B Deficiency Causes Respiratory Failure at Birth

SP-B deficiency is inherited in an autosomal recessive pattern, and most affected infants develop respiratory failure shortly after birth. While lung morphogenesis proceeds normally in utero, the lack of SP-B results in acute atelectasis and respiratory distress, usually presenting as full-term infants with signs and symptoms of diffuse alveolar collapse after birth. More than 40 distinct *SFTPB* mutations in patients with SP-B deficiency have been identified.[25,27] The disorder is refractory to surfactant replacement therapy, and most patients die from respiratory failure within several months after birth, requiring oxygen and ventilatory support throughout their clinical course. Lung transplantation has been offered to some patients. SP-B deficiency disrupts the formation of lamellar bodies and tubular myelin and interferes with the processing of proSP-C to the active peptide. Thus, most SP-B deficient patients lack both SP-B and SP-C peptides in the alveolus. In patients with *SFTPB*-related disease, proSP-C accumulates in the airspaces, contributing to an alveolar proteinosis–like syndrome. Pathologic diagnoses include desquamating interstitial pneumonitis, chronic pneumonitis of infancy or infantile alveolar proteinosis, and histologic changes being influenced by age and supportive therapies (Fig. 5-3).[28] The definitive diagnosis is made by identification of *SFTPB* gene mutations, enabling prenatal diagnosis and genetic counseling. While various missense, nonsense, frameshift, and splice variants have been identified, mutation 121ins2 in exon 4 is the most common.[24] In most affected infants, SP-B is lacking in bronchoalveolar lavage fluid and the abnormal proSP-C peptide accumulates in the alveoli, findings that can be verified by immunohistochemistry. Patients with SP-B deficiency do not respond to surfactant replacement and generally succumb from chronic respiratory failure early in infancy in spite of intensive care. A number of SP-B-deficient infants have been treated successfully by lung transplantation. Recent published data demonstrated efficacy of adeno-associated virus (AAV)-mediated gene rescue of SP-B deficiency in a transgenic mouse model.[29] These data, coupled with multiple ongoing clinical trials for AAV-mediated gene therapy approaches for other genetic diseases, pave the way for potential gene therapy approaches for SP-B-deficient patients in the future.

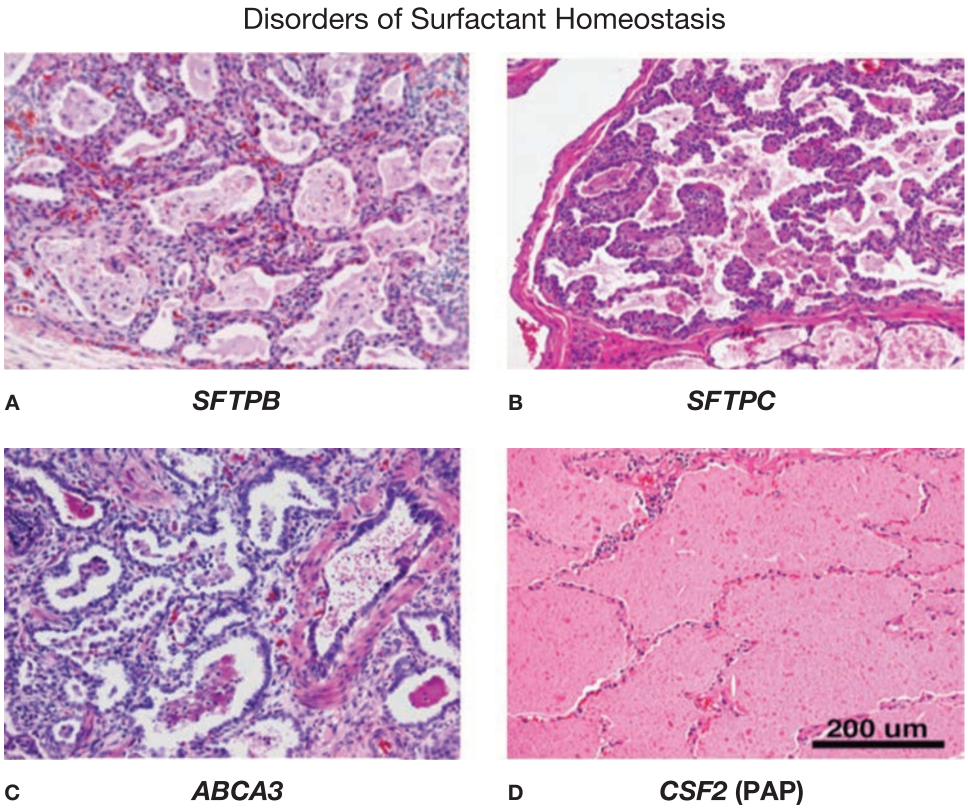

Figure 5-3 Pulmonary histopathology associated with disorders of surfactant homeostasis. Pathologic findings in neonates with mutations in *SFTPB*, *SFTPC*, and *ABCA3* are consistent with varying pathologic diagnoses, e.g., childhood interstitial pneumonitis (CIP), non-specific interstitial pneumonitis (NSIP), desquamating interstitial pneumonitis (DIP), or interstitial alveolar proteinosis (IAP). Severe alveolar remodeling, alveolar loss, macrophage infiltration, varying degrees of alveolar proteinosis, and stromal thickening are observed. In contrast, auto-antibodies against GM-CSF or mutations in the GM-CSF receptor (*CSFR2A*) are associated with pulmonary alveolar proteinosis (PAP) in which surfactant lipids and proteins accumulate in the alveolus. Alveolar structure is generally well maintained in PAP. *(Reproduced with permission from Whitsett JA, Wert SE, Trapnell BC. Genetic disorders influencing lung formation and function at birth. Hum Mol Genet. 2004;13(suppl 2):R207–R215.)*

Surfactant Protein C (SP-C)

In humans, SP-C is encoded by a single gene (*SFTPC*, OMIM 178620), located on human chromosome 8.[2,14] SP-C mRNA is expressed exclusively in AT2 cells in the lung and is translated to produce a 22-kDa precursor that is palmitoylated and proteolytically processed during intracellular transport to form the active, hydrophobic peptide of 35 amino acids stored in lamellar bodies.[2,3] After secretion, SP-C enhances the surface-active properties of lipid mixtures, lowering surface tension during compression and enhancing adsorption rate of lipid films at the air-water interface. Both SP-C and SP-B enhance the speed of formation and stability of lipid films. A mixture of surfactant lipids and proteins SP-B and SP-C improves lung inflation and compliance and is useful for treatment of respiratory distress syndrome in newborn infants. SP-C is palmitoylated on cysteine residues near the NH_2 terminus. The surface activity of depalmitoylated SP-C is somewhat less than that of palmitoylated SP-C, likely related to reduced stability of the α-helical domain that anchors the peptide within the lipid bilayer. Although the orientation of the palmitoyl groups in a lipid environment is not currently known with certainty, the lipid moiety on SP-C enhances the hydrophobicity of the amino-terminal region enabling its close contact with multilayered lipid films and likely serves to stabilize the α-helical, hydrophobic domain of SP-C. SP-C enhances the uptake of lipids by AT2 cells and plays an important role in lipid homeostasis in the alveoli.

In a lipid bilayer, the orientation of the α-helical segment of SP-C is closely parallel with the lipid acyl chains, implying a transbilayer orientation. In a surface monolayer, SP-C has a preferential orientation parallel to the interface, as observed by circular dichroism of monolayer films. The positive charges near the NH_2 terminus of SP-C may promote binding of phospholipid vesicles to the monolayer, a step required for insertion of phospholipids into the monolayer. SP-C forms well-defined domains within DPPC/DPPG films below the phase transition temperature of the bulk lipid. SP-C alters the size and shape of lipid vesicles, disrupting vesicular structures, causing the formation of larger vesicles and discoid particles.

Surfactant lipid films fold as a consequence of dynamic compression during the respiratory cycle in a process enhanced by SP-C and SP-B, each interacting with lipids in distinct ways. Interactions among SP-B and SP-C and disordered lipid phases enhance the surface tension–lowering properties of surfactant lipids. SP-B serves to stabilize the membrane-to-membrane interactions between the folded lipid layers to create multilayers.[3]

Role of SP-C in the Pathogenesis of Pulmonary Disease

Deletion of *Sftpc* in transgenic mice perturbed surfactant function and caused severe interstitial lung disease with advancing age.[30] While *Sftpc*$^{-/-}$ mice survive after birth,[31] the mice develop emphysema, pulmonary inflammation, and abnormal lipid accumulations in alveolar macrophages, epithelial, vascular, and stromal cells. Surfactant lipid spreading and stability are only modestly perturbed in the absence of SP-C in vivo. The severity of pulmonary disorder related to SP-C deficiency in mice is strongly influenced by genetic strain, age, and other injuries, indicating that both genetic and environmental factors influence lung structure and function in the absence of SP-C. SP-C binds bacterial endotoxin, supporting a role in innate host defense in the lung. SP-C-deficient mice are susceptible to viral and bacterial pathogens and develop severe pulmonary injury in mouse models of pulmonary fibrosis. The finding that "*Sftpc* gene deleted" mice develop an interstitial pulmonary disorder is consistent with findings in humans, wherein *SFTPC* mutations cause both acute and chronic lung disease.

Mutations in SFTPC Cause Severe Interstitial Lung Disease in Humans

Mutations in *SFTPC* represent a rare cause of acute and chronic lung disease in humans.[32,33] *SFTPC* mutations are generally inherited as an autosomal-dominant gene that has been causally linked to acute respiratory disease in newborn infants and, more commonly, to chronic interstitial lung disease in infants, children, and adults. De novo mutations in the *SFTPC* gene have been reported. The diagnosis of *SFTPC*-related lung disease (OMIM 610913) is usually made during infancy but can present later in life, the severity of disease varying in a single extended family.[33] Most mutations occur in the C-terminal BRICHOS domain of proSP-C that serves as an intramolecular chaperone for the metastable membrane-spanning helical domain.[34] The mutant proSP-C protein is misfolded and/or misrouted, resulting in intracellular accumulation and cell injury. Most mutations result in the lack of synthesis of the active SP-C peptide that may influence the pathogenesis of lung disease. Various forms of interstitial lung disease have been associated with the disease, including acute respiratory distress (RDS) in newborns, chronic pneumonitis of infancy (CPI), non-specific interstitial pneumonitis (NSIP), and other forms of idiopathic pulmonary fibrosis (IPF) (Fig. 5-3).[28] Lung histopathology associated with *SFTPC* mutations is likely influenced by age, duration and severity of the disease, treatment, and both genetic and environmental factors. Infants with *SFTPC* mutations often present with severe respiratory signs and symptoms following viral infections. Definitive diagnosis is made by identification of mutations in the *SFTPC* gene. The onset and severity of pulmonary disease in humans is highly variable, even in the same kindreds, indicating that genetic and environmental factors strongly influence the disorder. At present, there is no effective therapy for SP-C-related disease. Lung transplantation has been offered for treatment of hereditary *SFTPC* deficiency in patients with respiratory failure. Mutations in *SFTPC* are a rare cause of acute and chronic interstitial lung disease. More than 50 distinct mutations in *SFTPC* have been associated with clinical lung disease and include missense, frameshift, splice, insertions, and deletions that generally disrupt the structure of the C-terminal BRICHOS domain leading to rapid degradation of proSP-C by the proteasome. The most common mutation, I73T, is located in the linker domain (the region between the BRICHOS and transmembrane domains) and occurs in approximately one-third of patients. Unlike mutations in the BRICHOS domain, linker domain mutations do not lead to misfolding of proSP-C but rather alter intracellular trafficking and subsequent processing of the proprotein. Accumulation of proSP-C in a late endosomal compartment is associated with impaired autophagy that, in turn, may limit the ability of AT2 to respond to further injury.[35]

Expression of allele variants encoding SP-C has been linked to cytotoxicity and pathogenesis in several mouse models. Acute induction of an L188Q *SFTPC* transgene in adult mouse lung was associated with decreased repair capacity following lung injury.[36] Prenatal expression of a Δexon4 *SFTPC* transgene[37] or the C121G *Sftpc* allele[38] resulted in AT2 cell death, disrupted lung morphogenesis, and neonatal lethality. These mouse models confirmed in vitro findings of mutant SP-C toxicity but failed to model the human disease, which is not typically associated with postnatal lethality. Acute induction of expression of the I73T[39] or C121G *Sftpc* allele in adult lung resulted in interstitial lung disease marked by alveolitis, aberrant remodeling, and restrictive lung disease. These mouse models strongly linked expression of the mutant *Sftpc* allele to development of fibrotic lung disease and model the acute exacerbation phase of disease.

ABCA3 Mutations Cause Respiratory Failure at Birth

ABCA3 is a large, membrane-spanning transport protein that is present in the limiting membrane of lamellar bodies in AT2 cells (Fig. 5-2). More than 140 different mutations associated with severe lung disease in newborn infants have been identified, *ABCA3* mutations (OMIM 610921) representing the most common genetic cause of neonatal respiratory failure.[1,4,34,40] While expressed in many tissues, patients with mutations in *ABCA3* present with isolated lung disease, and abnormalities in other organ structures or functions have not been observed. Pathologic findings in newborn infants with respiratory failure are similar to those in mice wherein the *ABCA3* gene has been genetically deleted. *ABCA3* gene–related lung disease is generally inherited as an autosomal recessive disorder (Table 5-1). Affected infants present with severe respiratory failure characteristic of surfactant deficiency within the first days of life. Their lung disease is refractory to conventional therapies, resulting in respiratory failure and death within the first months of life. Pathologic findings are similar to those in *SFTPB*-related disease and include alveolar proteinosis, lipoidal pneumonia, cuboidal epithelial cell hyperplasia, interstitial thickening, loss of normal alveolar structures, and features of desquamating interstitial pneumonitis (DIP) (Fig. 5-3).[28] Older children present with features of NSIP (non-specific interstitial pneumonitis). In newborn infants, respiratory failure is not responsive to surfactant replacement. Lung transplantation has been successful for treatment of some patients with *ABCA3*-related diseases. ABCA3 is a member of the ATP-dependent Walker domain containing proteins that constitute a family of membrane-associated transport proteins that includes the CFTR (cystic fibrosis transmembrane conductance regulator). ABCA3 mediates phosphatidylcholine and phosphatidylglycerol transport into lamellar bodies. The diagnosis of ABCA3-related lung disease is confirmed by nucleotide sequencing of the gene in infants and children with refractory pulmonary disease. While most mutations cause respiratory failure in infancy, the E292V mutation is associated with less severe lung disease, and these patients often present with ILD later in childhood. Ultrastructural analysis of lung tissue from patients with *ABCA3* mutations usually demonstrates the presence of small, atypical lamellar bodies in AT2 cells and the absence of tubular myelin in the airways, indicating an abnormality in both intracellular and extracellular lipid homeostasis. The processing of proSP-B is disrupted in some patients with ABCA3-related lung disease.[25]

NKX2-1 in Surfactant Homeostasis

NKX2-1, encoding the homeodomain-containing nuclear transcription factor TTF-1 (thyroid transcription factor-1), plays a critical role in lung morphogenesis and the expression of surfactant proteins.[41,42] TTF-1 is expressed in the central nervous system, thyroid, and lung and is required for lung formation during embryonic development.[42] TTF-1 regulates the transcription of surfactant protein genes (*SFTPA*, *B*, *C*, and *D*), *ABCA3*, and *SLC34a2*, all expressed in AT2 cells.[41] *SLC34a2* is a phosphate transporter associated with the disease pulmonary alveolar microlithiasis.[43] Mutations in *NKX2-1* are linked to disorders of the central nervous system, thyroid, and lung (OMIM 600635), and more than 150 patients have been reported to date.[44,45] *NKX2-1* gene–related lung disorders are generally inherited as heterozygous mutations resulting in lung dysfunction of varying severity, ranging from disordered alveolar morphogenesis, surfactant deficiency with respiratory failure in neonates and infants, and interstitial lung disease in older patients. The majority of patients with *NKX2-1* mutations present with severe lung disease, approximately half of which have a spectrum of brain, thyroid, and lung disease. Histologic findings vary greatly, with severe abnormalities in the alveoli and variable loss of surfactant proteins and lipids. Pulmonary disease associated with *NKX2-1* mutations is frequently accompanied by congenital hypothyroidism. The severity of *NKX2-1*-related CNS, thyroid, and pulmonary disease varies widely. Diagnosis is made by identification of mutations in the *NKX2-1* gene. Heterozygous mutations in the *NKX2-1* gene have been associated with neuroendocrine hyperplasia.[46]

The Pulmonary Collectins (SP-A and SP-D)

The collectins SP-A and SP-D are critical components of the pulmonary surfactant system. The collectins are a group of highly conserved proteins expressed in many tissues that share functional domains, including helical collagenous and C-type lectin domains that bind to complex carbohydrates on pathogens and their products. A number of recent reviews summarize the roles of acquired immunity.[6,47] SP-A and SP-D bind and aggregate microbial pathogens, enhancing mucociliary clearance and opsonization by alveolar macrophages, serving to inhibit damaging inflammatory responses. Both proteins play important roles in surfactant homeostasis in the alveoli, interacting with lipids and proteins to regulate surfactant structures and pool sizes. SP-A and SP-D interact with a diversity of cells in the alveolus including macrophages, neutrophils, and eosinophils to regulate inflammation. SP-A and SP-D bind to and influence signaling via CD14, TLR2, LAIR-1, and SPR-210 to regulate phagocytosis or in professional immune cells.

Surfactant Protein A (SP-A)

SP-A is an abundant hydrophilic 26-kDa (monomer) glycoprotein that functions in the host defense and regulation of extracellular surfactant lipid structure. SP-A mRNA is expressed in non-ciliated bronchiolar and AT2 cells in the lung, being transcribed from two genes (*SFTPA1* and 2) located on chromosome 10 in the human.[2,13,18] SP-A in combination with SP-B and SP-C enhances formation of a surface lipid film in the presence of divalent ions but is not critical for surfactant activity in the alveoli. The amino-terminal third of SP-A is arranged in a collagen-like triple helix, while a carboxy-terminal region has structural similarity to mammalian lectins including SP-D, serum mannose-binding lectin (MBL), and C1q. Protein-protein interactions among SP-A molecules are mediated by the collagen-like domains via intermolecular disulfide bonds that are necessary for SP-A-mediated aggregation of lipids and formation of tubular myelin. SP-A trimers further oligomerize to form octadecamers that enhance cooperative interactions with glycoproteins and glycolipids on the surface of microbial pathogens. Binding and uptake of SP-A by AT2 cells and alveolar macrophages are mediated by specific cell-surface receptors; however, the precise nature of the SP-A receptors and their intracellular functions remain unclear.[48] Both collagenous and noncollagenous domains of SP-A bind to isolated AT2 cells and immune cells. SP-A increases the association of lipids with AT2 cells but does not appear to increase internalization of lipid. Deletion of the SP-A gene (*Sftpa*) in mice does not alter survival or lung function after birth. While tubular myelin is absent, surfactant function, uptake, and secretion are not strongly influenced by deletion of *Sftpa* in mice.[49] Nevertheless, $Sftpa^{-/-}$ mice are highly susceptible to lung infections by bacterial, viral, and fungal pathogens, indicating that SP-A plays an important role in innate host defense of the lung.[2,13,18]

Usual Interstitial Pulmonary (UIP) Disease Caused by Mutations in SFTPA2

Missense mutations in the genes encoding SP-A (*SFTPA1* and *SFTPA2*) have been linked to pulmonary fibrosis pathologically diagnosed as UIP (OMIM 178642), generally presenting as interstitial lung disease (ILD) in the 4th and 5th decade of life.[50,51] Increased risk of pulmonary adenocarcinoma was observed at more advanced ages. This rare disorder is inherited as an autosomal dominant mutation in which the oligomerization and intracellular trafficking of SP-A is disturbed, resulting in the unfolded protein response and chronic alveolar cell injury. Transgenic knock-in mice expressing the human *SFTPA1* mutation associated with ILD resulted in spontaneous fibrosis associated with necroptosis of AT2 cells[52] demonstrating a causal relationship between *SFTPA1* mutations and ILD.

Surfactant Protein D (SP-D)

Surfactant protein D is a collagenous Ca^{2+}-dependent carbohydrate-binding protein that is structurally related to SP-A and other C-type lectins.[18] SP-D is encoded by a single gene (*SFTPD*) located near the *SFTPA* genes on human chromosome 10.[2,13,18] SP-D is synthesized by AT2 cells and non-ciliated bronchiolar cells in the lung, but it is also expressed in many other tissues. SP-D trimers form larger oligomers that bind carbohydrates and glycolipids on the surface of bacteria, fungi, and viruses. The interaction of SP-D with microbial pathogens is Ca^{2+}- and carbohydrate-dependent.[18] In contrast to other surfactant proteins (SP-A, SP-B, and SP-C), SP-D is not strongly associated with surfactant lipids in the alveolus but plays an important role in determining surfactant structure and homeostasis.

■ Functions of SP-D In Vivo

Deletion of *Sftpd* in mice has provided insight into its important role in surfactant and alveolar homeostasis. *Sftpd*$^{-/-}$ mice survive after birth but develop severe pulmonary disease associated with macrophage activation, airspace enlargement, and marked accumulation of surfactant lipids in the alveoli.[53,54] SP-D regulates alveolar pools of large and small aggregate surfactant, influencing surfactant particle size and its uptake by AT2 cells. Addition of SP-D to surfactant lipid extracts enhances surfactant stability in vitro and protects the preterm lung from endotoxin-induced injury. Infiltration with lipid-laden macrophages, and the induction of synthesis of metalloproteinases 2, 9, and 12 by alveolar macrophages, may contribute to the spontaneous airspace remodeling seen in the *Sftpd*$^{-/-}$ mice. *Sftpd*$^{-/-}$ mice are highly susceptible to pulmonary infections and inflammation associated with viral (respiratory syncytial and influenza virus), bacteria and endotoxin, or fungal exposures, indicating that SP-D plays a critical role in innate host defense of the lung.[2,13,18] SP-D binds bacterial, fungal, and viral pathogens, enhancing their opsonization and their killing by alveolar macrophages. Levels of SP-D are low in preterm infants and in infants and older patients with chronic lung disease. SP-D influences immunologic responses to allergens, interacting with alveolar macrophages and lymphocytes in the innate immune system. Thus, SP-D plays an important role in the regulation of surfactant lipid homeostasis, innate host defense of the lung, and prevention of inflammation and alveolar remodeling. Susceptibility to influenza A viral infections has been linked to specific *SFTPD* alleles, but to date, mutations in *SFTPD* have not been directly linked to acute or chronic lung disease. Serum SP-D levels are increased in COPD, PAP, and other chronic and acute lung diseases and have been utilized in clinical settings to monitor disease progression and response to therapy.[55]

RECYCLING AND CATABOLISM OF SURFACTANT LIPIDS AND PROTEINS

Pulmonary surfactant is taken up rapidly in the lung, and much of the lipid is reutilized (Fig. 5-2). After intratracheal administration, labeled lipid appears in AT2 cells and alveolar macrophages, but is not found in type I cells, indicating that the AT2 cells actively take up surfactant lipids from the alveolus for recycling or catabolism. Isolated epithelial AT2 alveolar cells internalize H-PC and re-secrete the internalized material or degrade it with subsequent reincorporation into other lipids. Isolated primary AT2 cells endocytose SP-C and SP-B. SP-A also binds to AT2 epithelial cells and is endocytosed by receptor-mediated mechanisms. While a number of candidate SP-A and SP-D receptors and binding proteins have been identified, whether the proteins are efficiently recycled and the mechanisms by which they signal to influence surfactant homeostasis remain unclear.

Pulmonary surfactant as isolated from lavage fluid exists in several forms that can be fractionated based on density. In vivo labeling indicates that phospholipid is initially secreted in the heaviest forms, followed by conversion into distinct heavy and light forms. The densest or ultraheavy form contains lamellar bodies and tubular myelin. Small aggregate forms are comprised of small unilamellar vesicles. While their lipid composition is similar to that of large aggregates, small aggregates are depleted of SP-A, SP-B, and SP-C, and lack surfactant function. SP-A and SP-D play important roles in the maintenance of the large aggregate surfactant structures. Cycling surfactant by expansion and contraction of a surface film in vitro converts lipids from large to small aggregates that are likely remnants destined for catabolism or recycling.[3]

REGULATION OF SURFACTANT PRODUCTION

The synthesis of pulmonary surfactant is subject to precise regulatory controls both during development and postnatally.[56] Surfactant phospholipid synthesis increases markedly in late gestation and is enhanced by a variety of hormones, including glucocorticoids in the fetal lung. Lung phospholipid content increases in the latter two-thirds of gestation in preparation for respiratory adaptation at birth. Prenatal glucocorticoids are routinely used to induce lung maturation and surfactant synthesis in infants at risk for preterm delivery.[9] Glucocorticoids reduce the risk of IRDS, enhancing the structural maturation of the alveoli and the efficacy of surfactant replacement therapy after birth. Like surfactant phospholipids, the surfactant proteins are highly regulated, increasing in the latter two-thirds of gestation in the mammalian species studied. Expression of surfactant proteins is regulated in complex ways by a variety of hormonal agents. The levels of surfactant protein mRNA increase in the perinatal period in association with increased surfactant synthesis and secretion required for postnatal respiratory adaptation. Expression of the surfactant proteins is regulated at both transcriptional and posttranscriptional levels, maintaining steady-state protein concentrations within tight constraints in the adult lung. Surfactant production is, in general, enhanced by glucocorticoids, in a process mediated by lung fibroblasts, epidermal growth factor (EGF), and cyclic adenosine monophosphate (cAMP) but inhibited by tumor necrosis factor alpha (TNF-α), transforming growth factor beta (TGF-β), and insulin, depending on experimental conditions. Transcriptional control of the surfactant genes is modulated by a number of nuclear transcription factors, e.g., thyroid transcription factor 1 (TTF-1), cyclic AMP–responsive binding protein (CREBPα), members of the forkhead family transcription factors (FOXA2), retinoic acid receptors (RARs), sterol responsive element binding protein (SREBP), GATA binding proteins, Krupple factor 5 (KLF-5), NFATC3, and co-activators associated with the transcription factor.[57] In the lung, surfactant proteins A, B, and D are expressed in non-ciliated bronchiolar and AT2 cells, while SP-C is expressed exclusively in AT2 cells in the lung. Transcriptional, epigenetic, and posttranscriptional mechanisms influence the synthesis of surfactant proteins and lipids, regulating surfactant concentrations in the airspace during development and repair.

■ Surfactant Secretion

Lamellar bodies containing surfactant proteins SP-B and SP-C and lipids are secreted into the alveoli in a process mediated by activation of β-adrenergic receptors and P2X7R purinergic receptors that regulate intracellular cAMP and calcium homeostasis to influence cytoskeletal organization and secretion.[58] SP-B may regulate surfactant secretion mediated by Ca^{2+} and purinoreceptor activation.[23] Recent studies support a role for the orphan G protein–coupled receptor GPR116 in the regulation of surfactant secretion. Loss of GPR116 results in increased surfactant secretion, decreased surfactant uptake by AT2 cells, and increased alveoli surfactant pool sizes.[59] While secretion of surfactant lipids SP-B and SP-C occurs via lamellar bodies, secretion of surfactant-associated proteins SP-A and SP-D occurs via a distinct, secretory pathway (Fig. 5-2). Interactions of SP-A and SP-D with lipids occur after their secretion into the alveoli.

GM-CSF Signaling Regulates Surfactant Clearance

Mutations in the genes encoding GM-CSF receptors (*CSFR2A* and *CSFR2B,* OMIM 13899) and autoantibodies against CSF2 (GM-CSF) have been associated with early-onset pulmonary alveolar proteinosis in children and in adults, respectively.[5,60] While less than 10% to 15% of surfactant lipids is cleared by catabolism in alveolar macrophages, this pathway is critical in controlling steady-state surfactant concentrations in vivo. Granulocyte macrophage colony-stimulating factor (GM-CSF or *CSF2*) and GM-CSF receptors are required for normal surfactant catabolism by alveolar macrophages.[5,61] Surfactant protein and lipid clearance are decreased in *Csf2*, *Csfr2a*, and *Csfr2b* gene-deleted mice, causing pulmonary alveolar proteinosis in which surfactant proteins and phospholipids accumulate in the lung. Findings in the mouse models led to the discovery that GM-CSF signaling abnormalities cause idiopathic pulmonary alveolar proteinosis (PAP).[5,62] Clinical studies demonstrate that idiopathic PAP in adults is usually caused by autoantibodies against GM-CSF.[60] Similar abnormalities in surfactant homeostasis and alveolar macrophage morphology and function are observed in patients with PAP, whether caused by mutations in GM-CSF receptors or by neutralization of GM-CSF by autoantibodies. While surfactant components are taken up by alveolar macrophages in PAP, lipid metabolic products, in particular cholesterol and cholesterol esters, accumulate in AMs causing cell toxicity. Lung lavage and GM-CSF, given systemically or by aerosol, have been successfully used to treat adults with PAP (see Chapter 70).

SURFACTANT HOMEOSTASIS AND REPLACEMENT IN INFANTILE RESPIRATORY DISTRESS SYNDROME (IRDS)

Infantile respiratory distress syndrome is associated with prematurity, the risk increasing as gestational age decreases. In addition to the morphologic immaturity of the respiratory tract, lung phospholipid content and surfactant secretion are decreased in preterm infants. While functional surfactant can be isolated from infants with IRDS, surfactant pool sizes are markedly decreased in the preterm compared to the term infant, and the surface activity of surfactant from infants with IRDS is decreased. Alveolar-capillary leak of blood or serum proteins inactivates surfactant function. Decreased alveolar surfactant activity associated with pulmonary immaturity causes atelectasis, alveolar collapse, pulmonary hemorrhage, and hypoxemia in preterm infants. A schematic representing factors influencing the pathogenesis of IRDS is provided in Fig. 5-4.[63]

Supplemental oxygen and mechanical or assisted ventilation is routinely used to treat IRDS. Widespread use of exogenous surfactant has ameliorated the morbidity and mortality associated with IRDS in preterm infants. Exogenous surfactants—in the form of synthetic mixtures of phospholipids and extracts of lung or surfactant containing bovine or porcine surfactant proteins B, C, and phospholipids—have been used extensively for prevention and therapy of RDS in newborn infants.[64] Surfactant replacements with preparations containing surfactant proteins B and C act rapidly, increasing lung volumes and compliance and decreasing the requirements for positive-pressure ventilation and oxygen. Morbidity and mortality from IRDS have been markedly reduced since the application of surfactant replacement for preterm neonates, decreasing lung injury, pneumothorax, and mortality. Surfactant replacement is given intratracheally, resulting in improved lung function and oxygenation. Treatment with protein-containing surfactants was effective in decreasing morbidity and mortality from IRDS in clinical studies. Animal-based surfactant preparations containing SP-B and SP-C are now standard treatment for IRDS. The effectiveness of surfactant therapy is likely related to the immediate surface tension–reducing properties and to the reuptake and reutilization of the exogenous surfactant lipids by the respiratory epithelium. Following preterm birth, production of endogenous surfactant lipids and proteins by the respiratory epithelium is rapidly induced; therefore surfactant replacement is primarily utilized in the first few days following birth. Surfactant replacement has been used off-label in the treatment of meconium aspiration and pneumonia in neonates.

SURFACTANT HOMEOSTASIS IN ADULT RESPIRATORY DISTRESS SYNDROME (ARDS)

Adult respiratory distress syndrome occurs in association with trauma, sepsis, long bone fractures, thermal burns, and injury to the lung from aspiration of gastric contents, pneumonia, inhalation of toxic gases, and infection (see Chapter 140). In ARDS, increased permeability of the microvasculature permits leakage of protein and fluid into the lung, inactivating surfactant. Epithelial cell injury also may contribute to surfactant deficiency in ARDS. Various non-surfactant proteins and lipids present in elevated concentrations in the lung in ARDS have been implicated in reducing surface activity of pulmonary surfactant; these include immunoglobulins, albumin, fibrinogen, fatty acids, lyso-phosphatidylcholine, and C-reactive protein. The mechanisms causing the decrease in surfactant activity in ARDS include competition of the proteins for the air-liquid interface, sequestration and dilution of surfactant in non-surface-active particles, and inhibition of surfactant protein and lipid synthesis and secretion. Alterations in surfactant composition occur during ARDS and may precede the development of respiratory failure.[65] Phospholipid, SP-A, and SP-B concentrations are decreased, and the minimum surface tension of surfactant tested in vitro is increased in patients at risk for ARDS. In ARDS, total phospholipid, phosphatidylcholine, phosphatidylglycerol, and surfactant proteins SP-A and SP-B are decreased and the ratio of small to large aggregates is significantly increased compared with that in non-ARDS patients. Thus, ARDS leads to both a deficiency in pulmonary surfactant

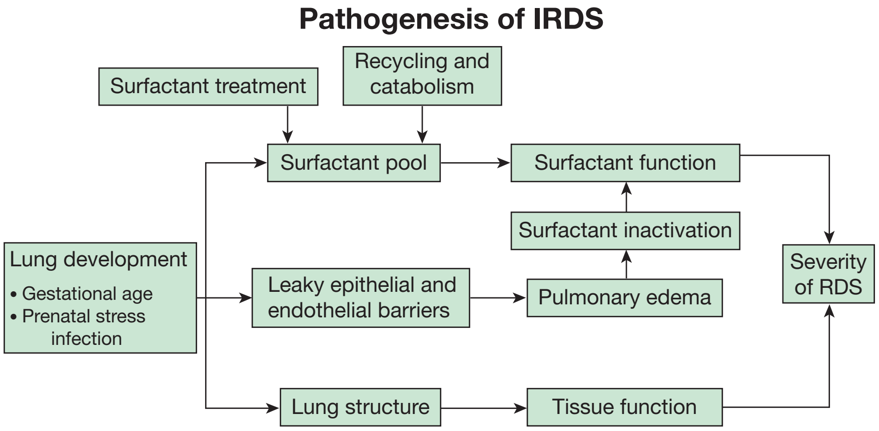

Figure 5-4 Factors influencing the pathogenesis of idiopathic respiratory distress syndrome (IRDS). The pathogenesis of IRDS is multifactional. Immaturity of AT2 cells results in decreased surfactant pools. Lung collapse and injury are caused by surfactant deficiency. Alveolar damage causes leakage of serum proteins and edema that inactivate surfactant, increasing the severity of respiratory distress. Surfactant treatment reduces surface tension, restores phospholipid pool sizes, and improves alveolar-capillary leak to maintain surfactant function. *(Reproduced with permission from Dr. Alan Jobe.)*

constituents and inhibition of the activity of the remaining surfactant. While exogenous surfactant has been effective in decreasing ARDS severity in laboratory experiments, to date, clinical studies have not supported the routine use of surfactant replacement for RDS in adult patients. In contrast, application of careful ventilatory support and prone positioning of patients has improved outcomes in ARDS.

INHIBITION OF SURFACTANT ACTIVITY DURING LUNG INJURY

Phospholipases A2 and C and their products, fatty acids, lysoPC, and dipalmitin inhibit surface activity in vitro. These molecules may be released or produced during lung injury. Inhibitory effects of oleic acid may be related to its miscibility with phospholipids, disrupting the interfacial surfactant film, rather than by competition for the interface. The inhibition by PAF, lysoPC, and oleic acid is not reversible, suggesting that their direct interaction with surfactant lipids disrupts lipid organization required for stable film formation. In contrast, palmitic acid improves surfactant function of preparations used for therapy of IRDS. The surface activity of pulmonary surfactant is readily destroyed by phospholipase A_2 or phospholipase C. Oxygen therapy, used routinely for ARDS and IRDS, may influence surfactant homeostasis and function in the alveolus. The rate of synthesis of surfactant lipids and clearance of radiolabeled surfactant extracts decreased in rabbits exposed to 100% O_2 for 64 h. In contrast, exposure of adult rats to 85% O_2 increased expression of surfactant proteins SP-A, SP-B, and SP-C and phospholipids. Oxidants are also released locally in the lung by activated immune cells. Activated alveolar macrophages secrete NO and superoxide, which can then react to form peroxynitrite that can oxidize and inactivate proteins and lipids. Peroxynitrite inhibited the surface activity of surfactant, damaging both lipids and surfactant proteins.

■ Plasma Proteins Inactivate Pulmonary Surfactant

Edema fluid leaks into the airspace in both ARDS and IRDS. Edema fluid obtained from hyperoxia-exposed rabbits contains serum proteins capable of inhibiting surface activity of surfactant extracts, as evaluated in the pulsating bubble apparatus. Thus, edema fluid may interfere with surfactant therapy, although the concentration dependence of the inhibition suggests that increased doses of surfactant may aid in overcoming the inhibitory effects of edema fluid. Serum albumin, globulin, and fibrinogen reduce the rate of adsorption, increase the minimum surface tension of the surfactant film, and reduce the hysteresis area between compression and expansion curves in vitro. The mechanism by which plasma proteins inhibit the activity of pulmonary surfactant is likely to be one of competition for the interface, because higher surfactant lipid concentrations overcome albumin inhibition even at high albumin concentrations. Inhibition by C-reactive protein, fibrinogen, and other plasma proteins is reversible. Addition of SP-A and organic surfactant extracts reverses inhibition caused by soluble proteins but not by lysoPC. Both SP-C and SP-B increase the ability of a phospholipid mixture to resist inhibition of surface activity by plasma proteins. SP-B is more effective than SP-C at resisting inhibition by fibrinogen. Optimal resistance to surfactant inhibition by serum protein was observed when both SP-C and SP-B were present.

REDUCTION OF SURFACTANT SYNTHESIS IN ARDS

In addition to the inactivation of pulmonary surfactant by proteins and lipids in edema fluid, a reduction of synthesis of surfactant may contribute to the decreased surfactant activity in ARDS. *Escherichia coli* endotoxin inhibited surfactant synthesis in lung organ cultures. Synthesis of surfactant proteins is also influenced by inflammatory responses following lung injury or infection. TNF-α decreased de novo synthesis of SP-A, SP-B, and SP-C mRNA and caused respiratory distress when administered intratracheally to the mouse. TGF-β1, produced during lung injury, decreased the expression of SP-A and SP-C in vitro. Thus, sepsis or lung injury may reduce both the synthesis and functions of surfactant lipids and proteins.

SUMMARY

Pulmonary surfactant is required for air breathing after birth and for protection of the lung from microbial pathogens and toxicants. Surfactant homeostasis requires the integrated functions of surfactant proteins and lipids to reduce surface tension in the alveolus. Decreased production or inactivation of pulmonary surfactant has been associated with both IRDS and ARDS. Mutations in genes mediating surfactant synthesis or catabolism (*ABCA3*, *SFTPA*, *SFTPB*, *SFTPC*, *NKX2-1*, and *CSFR2A/B* receptors) are rare genetic causes of acute or chronic lung diseases.[1–5,27,66] Identification of the genes and proteins mediating alveolar homeostasis provides the knowledge and tools to diagnose and treat rare lung diseases caused by disorders of surfactant homeostasis.

CHAPTER 6

Mucociliary Clearance

Thomas W. Ferkol
John D. Dickinson
Burton F. Dickey

INTRODUCTION

Mucus forms an essential barrier that protects the lungs from inhaled particles, pathogens, and toxicants. However, excessive mucus accumulation contributes to the pathogenesis of all the common diseases of the airways. Therefore, understanding airway mucus function and dysfunction is important for pulmonary medicine. The airway mucus barrier is mobile, continually propelled in a proximal direction by ciliary beating. Ciliary dysfunction causes disease both because of the failure to clear xenobiotics from the lungs and by causing mucus accumulation. Mucus and ciliary biology will be considered together in this chapter as they interact to achieve, or fail to achieve, airway clearance.

MUCOCILIARY CLEARANCE IN HEALTH

Below we consider the roles of airway surface liquid, surface epithelial cells, submucosal glands, and mucociliary and cough clearance in healthy individuals.

■ Airway Surface Liquid (ASL)

Liquid in the airway lumen is distributed between two distinct layers—a mobile mucus layer and a stationary periciliary layer (Fig. 6-1). Secreted polymeric mucins are the principal macromolecular components of the mucus layer, whereas membrane-tethered mucins and non-mucin glycoconjugates are the principal macromolecular components of the periciliary layer.

Mucus Layer

Normal mucus has physical characteristics on the border between a viscous fluid and a soft elastic solid. Its physical state can vary with the extent of hydration and other conditions as described below. Mucus is formed by a dilute network of mucin polymers in aqueous solution, with water accounting for $\sim$98% of the mass, salts $\sim$0.9%, globular proteins $\sim$0.6%, and mucins only $\sim$0.5%. Mucins are exceedingly large glycoproteins (monomeric masses up to 3×10^6 Da) that link up to form long chains and branched networks. MUC5AC and MUC5B are the major secreted mucins in the airways.[1–4] They exhibit similar molecular weights and primary structure (Fig. 6-2A) but differ in function (see "Secretory Cells," below) and polymer structure. Whereas MUC5B forms end-to-end polymers (Fig. 6-2B), emerging data suggest that MUC5AC forms branched covalent networks. They have characteristic regions rich in serine and threonine residues linked by their hydroxyl side groups to sugar chains (*O*-glycosylation) that account for 50% to 90% of the mass of mucins.

Mucins are packaged dehydrated in secretory granules. After secretion, they rapidly adsorb several hundred fold their mass of water, so it is critical there be sufficient airway surface liquid.[5] Insufficient liquid results in formation of a gel that is too viscoelastic and adhesive to be readily cleared by ciliary motion or cough. Once immobile mucus plaques are formed, they swell only very slowly if subsequently exposed to additional liquid because of the high degree of entanglement of the mucin polymers. Besides the need for sufficient surface liquid, determined mostly by the amount of chloride and sodium in the ASL, adequate bicarbonate must also be present to bind calcium and allow proper mucus swelling. In secretory granules, calcium organizes the folding of mucin polymers and must dissociate to allow mucus expansion.[6–8] Chloride and

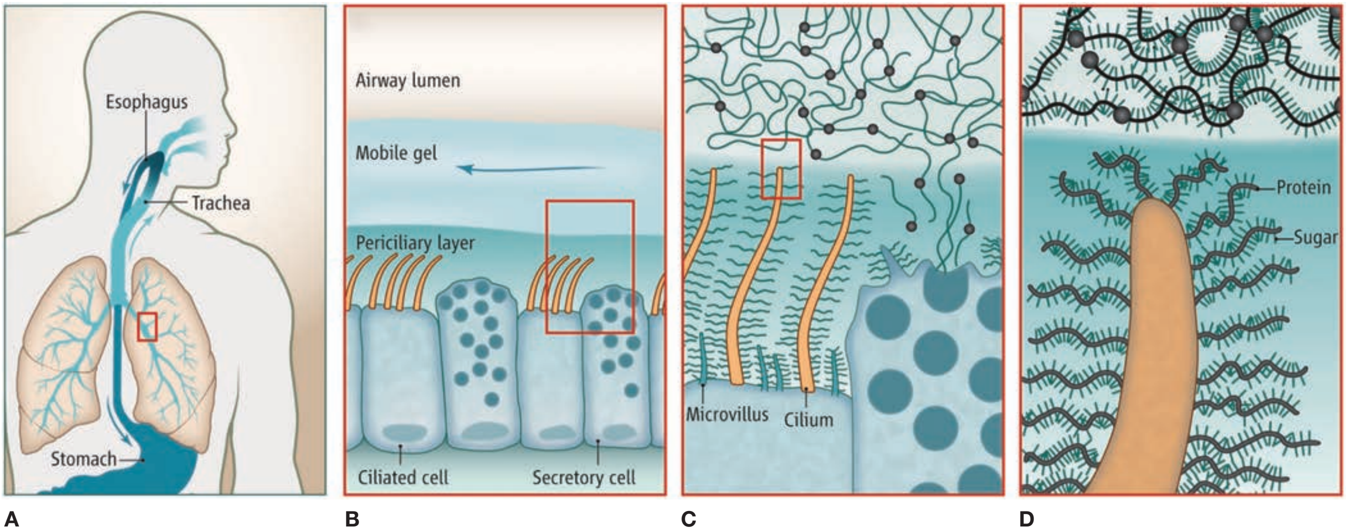

Figure 6-1 Airway surface liquid layers. **A.** Mucus is continuously produced in the conducting airways of the lungs, and swept by ciliary action from distal to proximal airways. After passing through the larynx, mucus is swallowed. **B.** The mobile mucus layer *(light blue)* glides over a periciliary layer of higher osmotic modulus *(dark blue)*. **C.** Airway secretory cells synthesize and secrete mucin polymers that interact with water to form the mobile mucus layer. Ciliated cells are covered by a dense glycocalyx containing glycosaminoglycans, membrane-tethered mucins, and other glycoconjugates that give the periciliary layer its high osmotic modulus. **D.** Mucin polymers are illustrated in the mucus layer with the protein core shown in *black*, sugar side chains in *blue*, and sites of end-to-end polymerization as *black circles*. Membrane-tethered mucins are shown densely coating cilia, while other glycoconjugates are not illustrated. *(Reproduced with permission from Dickey BF: Biochemistry. Walking on solid ground, Science. 2012;337(6097):924–925.)*

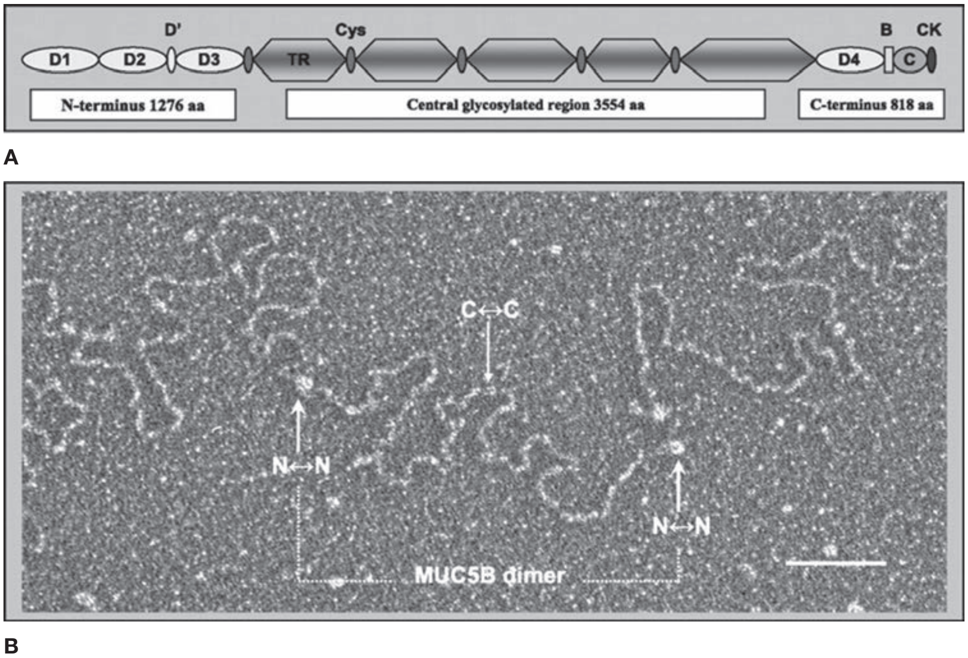

Figure 6-2 The structure of MUC5B. **A.** Structural domain representation of the MUC5B monomer. MUC5B has Von Willebrand factor (VWF)-like domains at NH_2 and COOH-terminal regions (D, B, C, and CK domains). The central region contains five heavily glycosylated, tandem repeat (TR), mucin domains, and five small cysteine-rich (Cys) regions. **B.** Electron microscopy image of a conformationally relaxed, linear MUC5B molecule. The MUC5B intact molecule in mucus is assembled from disulfide bond-mediated interactions between COOH-terminal domains of monomers to form dimers, and subsequent interactions between NH_2-terminal domains to form higher order polymers. The assignment of the structure as a dimer (dotted bar) is made on the basis of the length (850 nm), which is greater than that obtainable by a single MUC5B monomer. The N↔N terminal region and C↔C terminal region can be identified by their size. Scale bar, 100 nm. *(Reproduced with permission from Kesimer M1, Makhov AM, Griffith JD, et al. Unpacking a gel-forming mucin: a view of MUC5B organization after granular release. Am J Physiol Lung Cell Mol Physiol. 2010;298(1):L15–L22.)*

bicarbonate are both secreted into the airway lumen by the cystic fibrosis transmembrane conductance regulator (CFTR). Since the airway epithelium is quite water-permeable, water follows these anions into the airway lumen.[9] Additional hydration can be provided by other chloride channels as described below in the sections on Secretory Cells, Asthma, and Treatment.

Polymeric mucins are produced both in the superficial epithelium and in submucosal glands (Fig. 6-3). In the superficial epithelium, mucins are produced throughout the conducting airways down to the level of the smallest bronchi and the larger bronchioles, but not in terminal or respiratory bronchioles (Fig. 6-4A). Bronchioles lack submucosal glands, and overall, it is estimated that two-thirds of total airway mucus is produced by surface epithelial cells and one-third by submucosal glands in primates[10,11] (Fig. 6-4B). In the most distal airways, the mucus layer is vanishingly thin, but it becomes increasingly thick as it travels proximally, both because additional production adds to its bulk and because the total cross-sectional area of the airways progressively narrows. In the trachea, the mucus gel layer is approximately 50 μm thick. Besides mucus acting as a simple physical barrier in defense of the airway, the mucin sugar side chains act as a combinatorial library to bind particles and pathogens, and a thicker mucus layer has been shown to protect against infection.[12]

Periciliary Layer

It was widely believed until recently that cilia beat in a watery layer of lower density than the overlying mucus layer. However, recent data indicate that the periciliary layer has a higher density than the mucus layer due to a high concentration of membrane-tethered mucins (MUC 1, 4 and 16) and mucopolysaccharides (also called glycosaminoglycans).[13–15] This finding has several important implications for airway function:[4,16] (1) It helps to explain how distinct layers form because dense packing of the grafted glycoconjugates of the periciliary layer tends to exclude the unattached polymeric mucins of the mucus layer (Fig. 6-1C). (2) Charged polymers are highly effective lubricants in an aqueous environment, providing low friction between the periciliary and gel layers, and allowing low friction ciliary beating despite the high density of grafted glycoconjugates. (3) Spatial impingement by grafted glycoconjugates may physically couple neighboring cilia to coordinate their beating (Fig. 6-1C). (4) Glycoconjugates are grafted with increasing density from the top of the periciliary layer to the bottom, propelling exogenous particles and pathogens out of the periciliary layer for removal by the mobile mucus layer. (5) The higher density of water-avid glycoconjugates in the periciliary layer and their grafting to the cell surface results in a nearly constant amount of liquid in this layer except under conditions of severe underhydration. In conditions of overhydration, liquid is transferred to the mucus layer, which is generally well tolerated except with extreme dilution as some degree of viscoelasticity is required for cilia to move mucus against gravity.[17]

■ Airway Epithelial Cells

The surface airway epithelium is mostly a mosaic of two major cell types—secretory and ciliated cells (Figs. 6-1, 6-5, and 6-8). In addition, basal cells that do not contact the airway lumen serve as progenitors in the proximal airways, and scattered throughout the airways are neuroendocrine cells that secrete basolaterally toward sensory neurons, tuft cells that sense odorants, and ionocytes that express high levels of CFTR.[18] Secretory and ciliated cells have a tall columnar shape with a pseudostratified appearance in proximal airways but become progressively shorter in distal airways until they reach a cuboidal shape in bronchioles with a simple single-layer

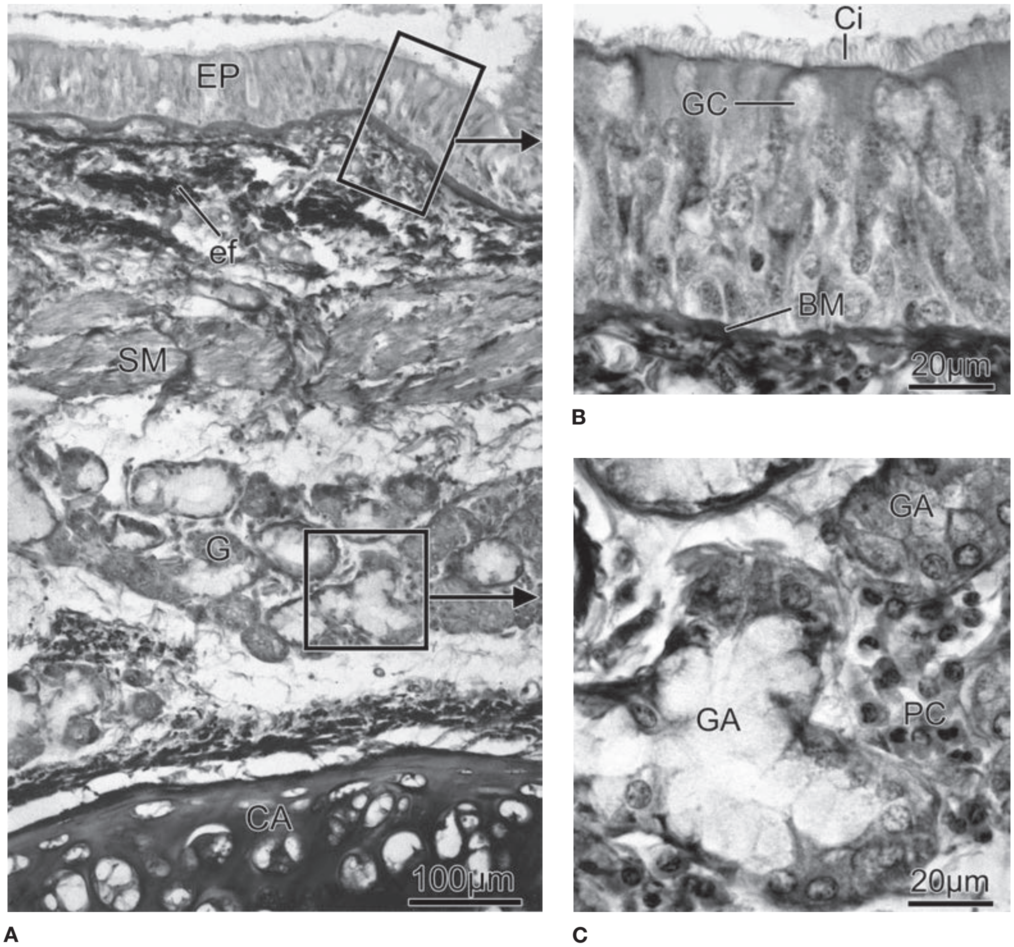

Figure 6-3 Light micrographs of bronchial wall. **A.** The layers from epithelium (EP) to cartilage (CA) with elastic fibers (ef), smooth muscle bundles (SM), and glands (G). **B.** Higher power view of pseudostratified epithelium with ciliated cells (Ci), goblet cells (GC), and basement membrane (BM). **C.** Details of gland acini (GA) associated with groups of plasma cells (PC).

appearance. Ciliated cells are more abundant than secretory cells in proximal airways, whereas secretory cells are more abundant in distal airways.

Secretory Cells

Subsets of airway secretory cells have been given different names based upon differences in their microscopical appearances, including goblet and club (Clara) cells. However, molecular techniques reveal overlap between these subsets, such as the presence of CCSP (SCGB1A1) in cells with a goblet morphology that express mucin, and the presence of MUC5B in cells with a club morphology.[11,19–21] The identity of secretory cells is unified by the stable expression of a regulated exocytic machinery at the apical surface[22,23] (Fig. 6-6), whereas the presence of secretory products such as mucins and secretoglobins varies along the proximal-distal axis and with exposure to extracellular signals that acutely regulate their expression and secretion. Therefore, it is simplest to refer to these cells generically as airway secretory cells, while further specifying their appearance, airway level, and gene expression profile as appropriate. Recently it has been found that CFTR is expressed in surface epithelial secretory cells throughout the airways.[24] Thus, these cells are “secretory” in the sense of apical secretion of both macromolecules and salt.

Secretory cells in bronchi and proximal bronchioles constitutively express MUC5B (Figs. 6-4 and 6-5), whereas secretory cells in terminal and more distal bronchioles do not express MUC5B either constitutively or inducibly.[1,11,19,25] The same secretory cells that express MUC5B can also express MUC5AC, with MUC5AC expressed constitutively in a small number of cells in proximal airways, but inducibly in large numbers of cells in both proximal and distal airways.[11] Mice with deletion of MUC5B often die postnatally from upper and lower respiratory tract inflammation and infection.[26] In contrast, mice with deletion of MUC5AC are healthy at baseline but have an impaired ability to trap parasitic worms transiting their lungs,[27] and induced expression of MUC5AC in rat lungs increases worm trapping.[22] Thus, MUC5B appears to be the principal mucin functioning in baseline clearance of particles and microbes from the airways, while MUC5AC appears to function principally in parasite defense. Notably, the level of expression of MUC5B in mice is limiting for particle clearance such that heterozygous mice have an approximately 50% rate of bead clearance, and MUC5B expression and bead clearance decline in parallel with age.[28] The relevance of these observations from mice for human pathophysiology is indicated by the occurrence of bronchiectasis, repeated airway infections with *Staphylococcus aureus*, and impaired lung function in two siblings with biallelic loss of MUC5B expression, subclinical abnormalities of lung function in two siblings with monoallelic loss of MUC5B expression, and genetic evidence of constraint against monoallelic loss-of-function variation in the general population.[29]

The effector function of MUC5AC in parasite defense dovetails well with the central role of IL-13 in parasite defense and the ability of IL-13 to strongly induce expression of MUC5AC (>100-fold in cultured human airway cells and 40-fold in mice in vivo).[30–32] Other cytokines that promote mucin gene expression include IL-1β, -4, -6, -9, -23, and -25. Among these, IL-1β has a central role in CF and COPD,[33] but whether the other cytokines signal directly or indirectly through IL-13 is not yet clear.[1] Complement protein C3a, epinephrine, and γ-aminobutyric acid signaling interact with IL-13 signaling to augment MUC5AC expression.[1] ClCa1 is a secreted protein that signals in an autocrine and paracrine fashion in response to IL-13 to increase MUC5AC expression.[30] A

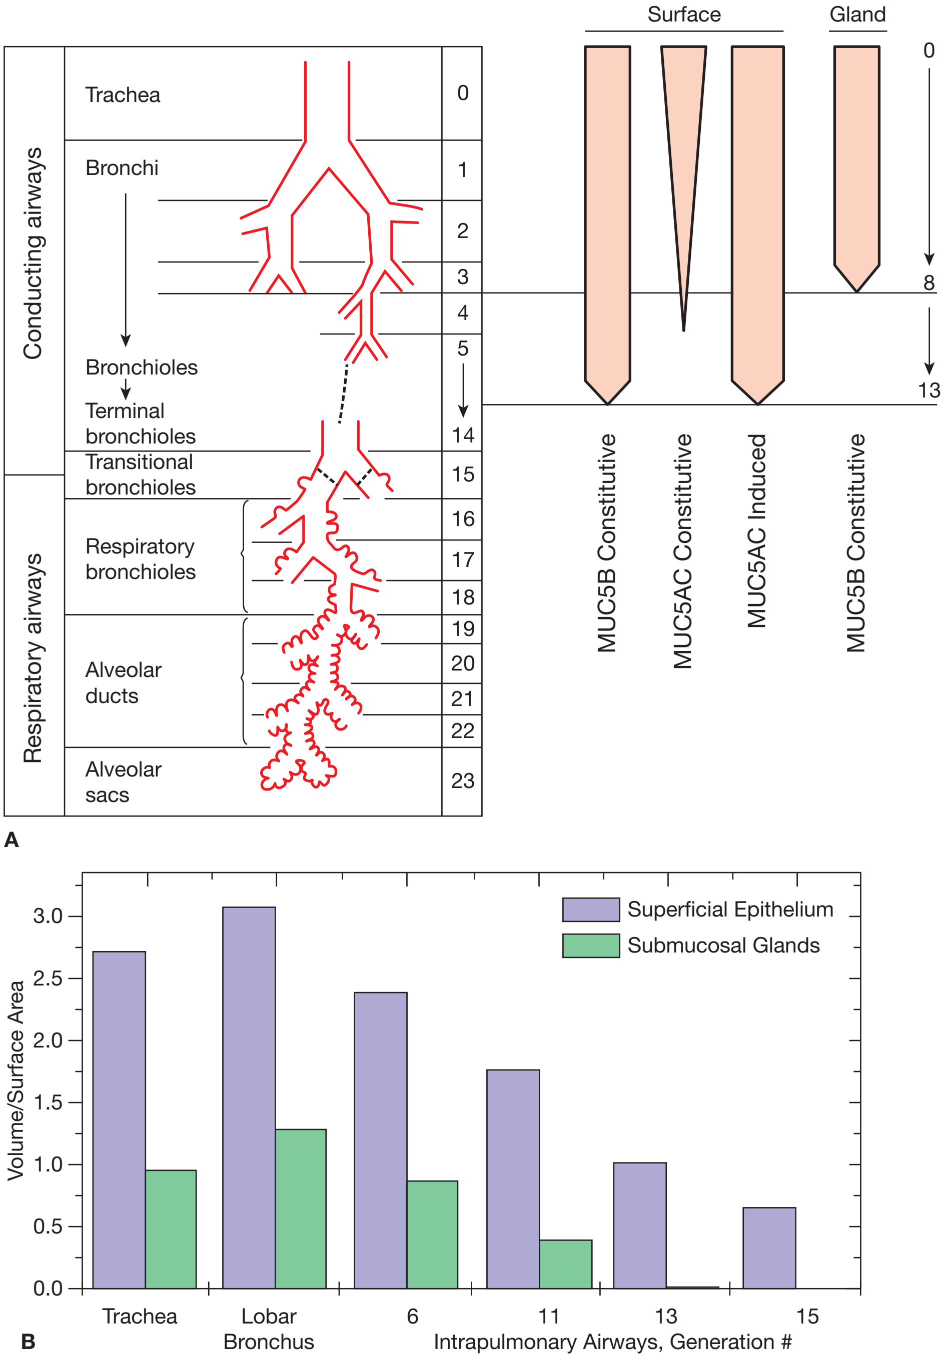

Figure 6-4 Mucin production in conducting airways. **A.** MUC5B is produced constitutively by surface epithelium down to the level of bronchioles proximal to terminal bronchioles, and by submucosal glands present in the trachea and bronchi but not bronchioles. MUC5AC is produced constitutively by surface epithelial cells with a goblet morphology in more proximal airways, and its production can be induced in nongoblet secretory cells that produce MUC5B down to the level of preterminal bronchioles. Airway generation is listed numerically in the third column. **B.** The relative amount of mucin produced by surface epithelium and submucosal glands has been estimated by morphometric analysis of the airways of rhesus monkeys stained with Alcian blue/PAS, expressed as the ratio of volume of stained material ($mm^3 \times 10^{-3}$) per unit area of basal lamina (mm^2). *(**A:** Modified with permission from Weibel ER: Morphometry of the Human Lung. Heidelberg: Springer-Verlag; 1963; **B:** Reproduced with permission from Plopper CG, Heidsiek JG, Weir AJ, et al. Tracheobronchial epithelium in the adult rhesus monkey: a quantitative histochemical and ultrastructural study, Am J Anat. 1989;184(1):31–40.)*

network of transcription factors has been identified that regulates MUC5AC expression, including STAT6, SPDEF, Foxa2, Foxa3, Notch, β-catenin, and XBP-1. While some components of the signaling pathways connecting extracellular ligands with transcriptional regulation are known, such as the key roles of STAT6 downstream of IL-13 and MAPK13 downstream of ClCa1,[30,34] other details remain to be elucidated. The regulation of MUC5B expression was less well studied until recently, reflecting its stable expression relative to MUC5AC. However, the discovery of MUC5B overexpression in interstitial lung diseases led to intensive analysis of its transcriptional control[35] (see "Interstitial Lung Diseases," below). Besides a core Sp1-dependent promoter,[36] there is a strong enhancer that interacts with FOX transcription factor family members and SPDEF, and is regulated epigenetically.[37] Along with production of the polymeric mucins themselves, specialized enzymes required for glycosylation (e.g., GalNAc-T),[38] folding and polymerization (e.g., AGR2),[39] and other aspects of mucin processing are produced by airway secretory cells.

Mucins are secreted into the airway lumen at a low basal rate and a high stimulated rate. A regulated exocytic mechanism mediates both rates as indicated by abnormal phenotypes in both basal and stimulated secretion when Munc13-2, a sensor of second messengers, is deleted in mice.[20] Additional molecular components of the exocytic mechanism have been identified and their functions studied (Fig. 6-6).[22,23,40,41] Of particular interest are the Munc18 proteins because Munc18a participates primarily in basal secretion whereas Munc18b participates primarily in stimulated secretion, indicating that distinct molecular machines mediate mucin secretion at low and high rates.[42] The rate of mucin secretion is regulated by the second messengers, calcium and diacylglycerol, which are generated by a signaling cascade downstream of G protein–coupled receptors that include the $P2Y_2$ purinergic and A3 adenosine receptors.[22,43,44] ATP is released in

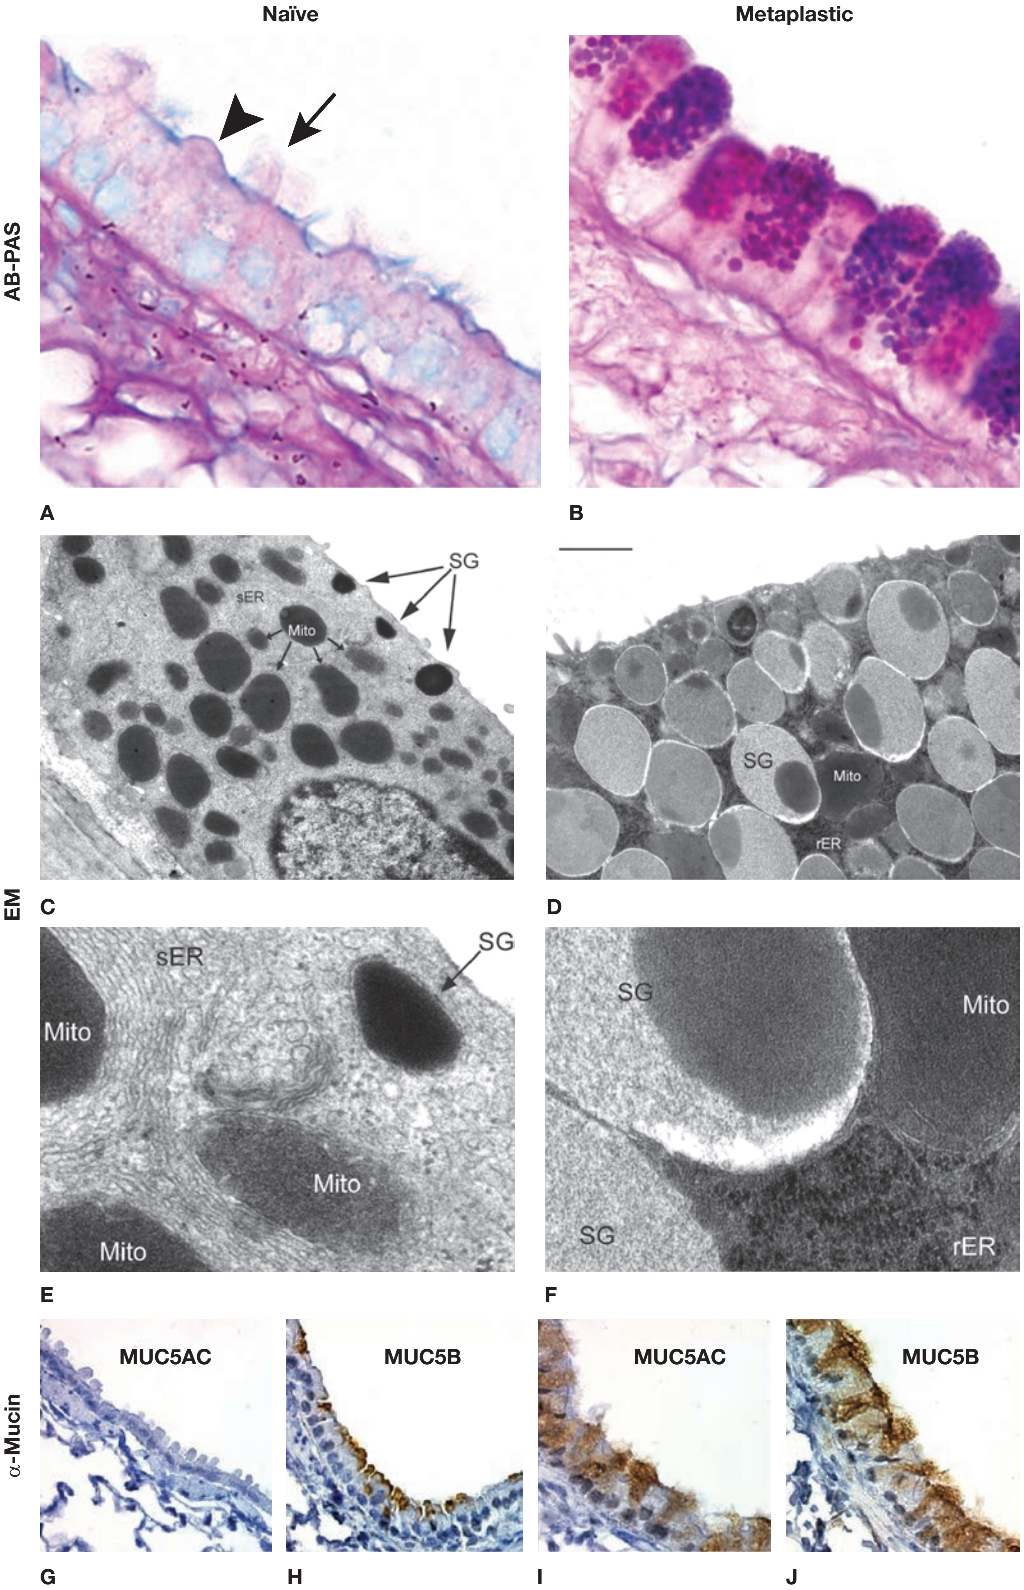

Figure 6-5 Airway epithelial mucus metaplasia. Light micrographs with AB-PAS staining (**A, B**), electron micrographs (EM) (**C–F**; low and high magnification), and immunohistochemical images using mucin-specific antibodies (**G–J**). On the left are images from the airway of a healthy mouse without airway inflammation (naïve), and on the right are images from the airway of a mouse with mucus metaplasia 3 days after the onset of allergic inflammation, as described by Evans et al.[19] Cells in the top row on the left show alternating ciliated *(arrow)* and domed secretory *(arrowhead)* cells, and on the right show prominent mucin granules in secretory cells. Cells in the EM images on the left show small numbers of electron-dense secretory granules (SG) near the apical membrane, numerous mitochondria (Mito), and abundant smooth endoplasmic reticulum (sER). Cells in the EM images on the right show numerous electron-lucent SG containing mucins and an electron-dense core, and abundant rough ER (rER). Images in the bottom row show that MUC5B is present in naïve airways even though it is not apparent by insensitive AB-PAS staining, and that both MUC5AC and MUC5B are present in the thickened metaplastic epithelium. Scale bar in the right middle panel is 10 μm for top row, 1 μm for second row, 150 nm for third row, and 30 μm for bottom row.

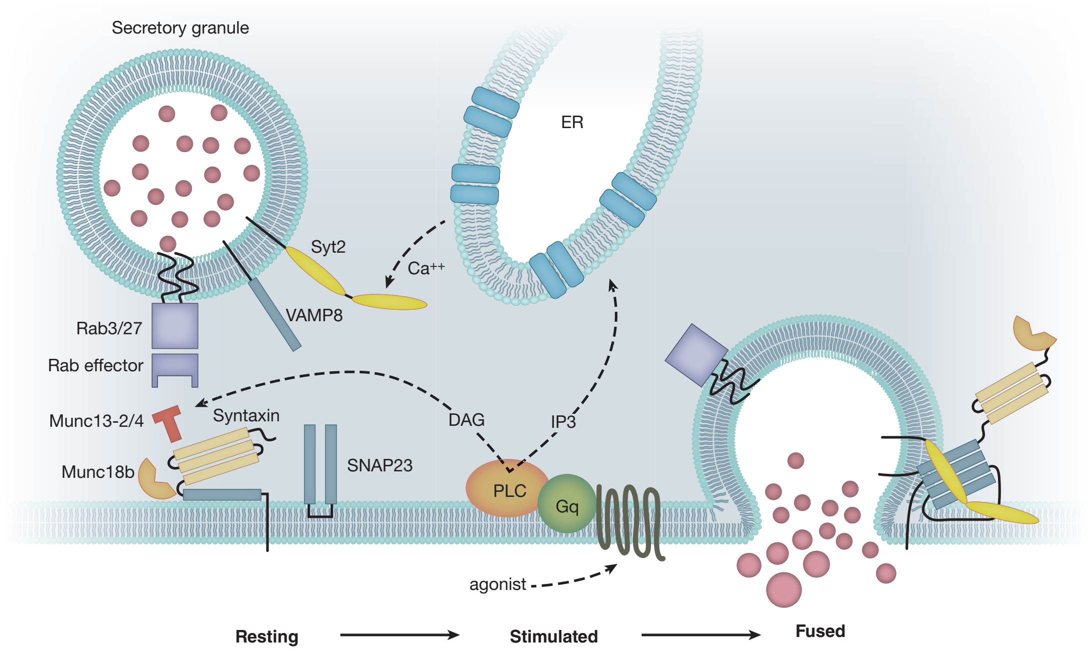

Figure 6-6 Airway mucin secretion. Initially, mucin granules become tethered to the plasma membrane by Rab proteins and their effectors in the vicinity of the exocytic SNARE proteins (VAMP8, SNAP23, and an unknown Syntaxin, shown as blue bars) *(Left)*. Activation of heptahelical receptors such as those for ATP (P2Y$_2$) and adenosine (A3R) leads to activation of the trimeric G-protein, Gq, and phospholipase C (PLC), resulting in generation of the second messengers diacylglycerol (DAG) and inositol trisphosphate (IP$_3$). Diacylglycerol activates the priming protein Munc13-2, and IP$_3$ induces the release of calcium from apical ER to activate Synaptotagmin-2 (Syt2) *(Center)*. Activation of the regulatory Munc13 and Syt proteins leads to full coiling of the SNARE proteins to induce fusion of the granule and plasma membranes. The interactions of the SNARE proteins take place on a scaffold provided by Munc18b *(Right)*. *(Adapted with permission from Davis CW, Dickey BF: Regulated airway goblet cell mucin secretion, Annu Rev Physiol. 2008;70:487–512.)*

autocrine and paracrine fashion, whereupon it activates P2Y$_2$ receptors and is metabolized to adenosine that actives A3 receptors. It is possible that additional ligands such as histamine and acetylcholine act as secretagogues during inflammation, although they may act indirectly by causing smooth muscle contraction and nucleotide release. Besides their release from intracellular stores by exocytic secretion, mucins can be degraded by autophagy upon cytokine withdrawal.[45]

Since secreted mucins must adsorb large volumes of water to yield mucus of normal viscoelasticity, it is important that adequate airway luminal water be available. The autocrine/paracrine ligands ATP, adenosine and ClCa1 regulate the expression and/or activity of CFTR, the calcium-activated chloride channel (CaCC) TMEM16A, and solute carrier family 26, member 9 (SLC26A9) to control chloride secretion.[30,43,46] Since these same ligands regulate mucin production and/or secretion as described above, mucin release is coordinately regulated with water translocation. Furthermore, recognition that CFTR is expressed predominantly in secretory cells in superficial epithelia suggests that mucin and ion secretion are coordinately regulated within a single cell,[24] with additional anion secretion in proximal airways provided by scattered ionocytes and submucosal glands. In small airways, longitudinal folds open and close during inspiration and expiration (Fig. 6-7). Mucin and ion

(with concomitant water) secretion are concentrated at the base of these furrows to form mucus of low viscoelasticity, while ion absorption is concentrated at the top of the ridges to prevent small airway flooding.[47] Identification of ion-secreting cells can be made either by expression of CFTR, which localizes to the apical membrane,[24] or by expression of the Na-K-Cl cotransporter, NKCC1, or the Na-HCO_3 cotransporter, NBC1, which localize to the basolateral membrane,[47] as these apical and basolateral ion conductances function in tandem.

Besides their role in mucin production and secretion, airway secretory cells serve as progenitors of both secretory and ciliated cells,[18,48] and express components of the cytochrome P450 system that inactivates toxic inhaled organic compounds by oxidation.[49] They also secrete antimicrobial peptides and reactive oxygen species at low levels constitutively, and are capable of sensing pathogens and responding by augmentation of their intrinsic antimicrobial defenses and signaling to leukocytes.[50]

Ciliated Cells

Motile cilia on the apical surface are the defining structural and functional feature of airway ciliated cells (Fig. 6-8) (Video 6-1). They are evolutionarily conserved and share homologous features with flagella of unicellular eukaryotes and mammalian sperm tails. Respiratory cilia have a “9+2” axonemal (microtubular) structure, which is composed of 9 peripheral doublets surrounding a central pair.[51,52] The outer doublets are linked together by proteins that form the dynein regulatory complex (“nexin link”), and radial spokes extend from the doublets to the central pair.[53] Taken together, these axonemal components provide the framework for generation of a complex ciliary waveform. The key components for driving ciliary movement are the inner and outer dynein arms, which are repetitive units present at regular intervals of 96 and 24 nm, respectively, along the length of the peripheral microtubules (doublets) and contain enzymes for ATP hydrolysis to generate force for dynein arm movement. Each cilium contains >300 different proteins and is rooted in the airway epithelial plasma membrane by a modified centriole, the basal body. Mutations in genes encoding many parts of the axonemal structure, or functional components of motile cilia, or components necessary for the biogenesis of cilia, including cytoplasmic proteins, can result in disease, including primary ciliary dyskinesia (PCD), as described below.

The function of normal motile cilia is to provide mucociliary clearance in the conducting airways, an important innate defense mechanism of the lungs.[54] Cilia provide the coordinated motive force for mechanically clearing mucus containing infectious agents, particles, and toxic substances from the conducting airways. ATP hydrolysis in the dynein arms produces sliding of adjacent axonemal structures and generates the complex ciliary waveform that occurs in human airways.[51,52] Approximately 200 cilia per cell beat in a coordinated fashion on and between cells. This coordinated vectorial synchrony results from the planar orientation that occurs during ciliogenesis, the tight packing of cilia in relation to large glycoproteins that coat their surfaces, longitudinal furrows in airways, and existing cilia-driven fluid flow.[13,47,55,56] The ciliary forward (power) stroke is more rapid and extends a bit more into the mucus layer than the recovery stroke.[55] Cilia beat at ~6–12 Hz, and propel mucus proximally at 1–5 mm/min. The regulation of ciliary beat frequency involves a variety of signaling molecules and multiple feedback mechanisms.[51,57] In brief, ciliary beat frequency and mucociliary clearance do not operate at full capacity under basal conditions but can be stimulated by several intracellular signaling mechanisms including cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) dependent phosphorylation of axonemal components, as well as changes in intracellular calcium and pH. In contrast, protein kinase C downregulates ciliary beat frequency. Infection or smoke exposure can negatively impact ciliary beating.[58]

Besides their role in moving the mucus layer, ciliated cells play additional crucial roles in airway homeostasis. They regulate mucin and fluid secretion by sensing multiple mechanical forces, including shear stress from airflow, stretch and compressive forces during inspiration and expiration, and cilial strain from interactions with overlying mucus of varying viscoelasticity.[59] Sensing these forces results in graded release of ATP from pannexin channels, which signals in a paracrine manner to neighboring secretory cells, both directly via $P2Y_2$ purinergic receptors and indirectly after metabolism via A2B and A3 adenosine receptors.[60] In addition, despite their terminal differentiation status, ciliated cells are capable of flattening to cover epithelial gaps when secretory cells are injured.[61]

■ Submucosal Glands

In bronchial airways, submucosal glands contribute to the secretion of mucins and liquid. The body of the gland is located between

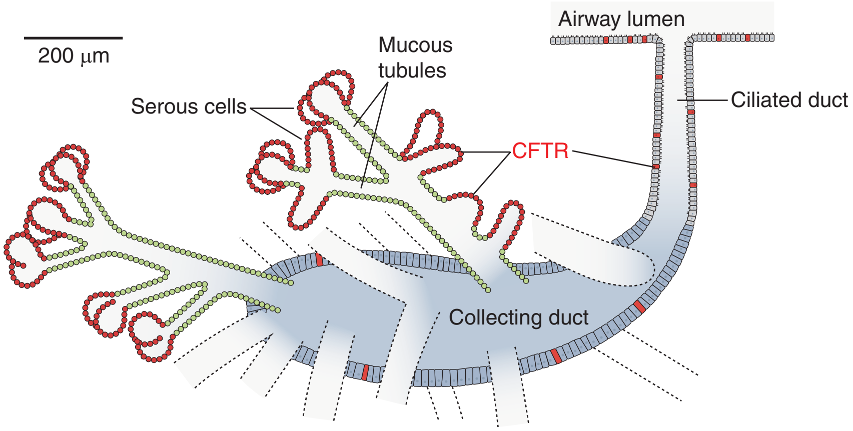

Figure 6-9 Diagram of a human bronchial submucosal gland. A single gland was reconstructed from serial cross sections. Only two of thirteen secretory tubules are illustrated, with the positions of the proximal portions of the others indicated by dotted lines. In the secretory tubules, serous cells expressing CFTR are shown in red, mucous cells are shown in green, and in the collecting duct, occasional ionocytes expressing CFTR are also shown in red. *(Reproduced with permission from Widdicombe JH, Wine JJ. Airway Gland Structure and Function. Physiol Rev. 2015;95(4):1241–1319.)*

spiral bands of smooth muscle and cartilage plates in the airway wall (Fig. 6-3). Each gland is connected to the airway lumen by a superficial ciliated duct that propels secretions outward and a deeper non-ciliated collecting duct[62] (Fig. 6-9). The body of the gland is composed of multiple mucous tubules that empty into the collecting duct, with serous cells that secrete fluid and antimicrobial peptides located in more distal acini. This spatial arrangement allows mucous cells, which constitute ~60% of the gland volume, to secrete mucins into a dilute, bicarbonate-rich liquid provided by serous cells, which constitute ~40% of the gland volume. Further anion secretion is provided by scattered ionocytes that express CFTR at high levels in the ducts.[24] Glandular mucous cells express MUC5B almost exclusively, with little or no expression of MUC5AC.[1,62] In pathologic states such as chronic obstructive pulmonary disease (COPD) and cystic fibrosis (CF), the volume and number of submucosal glands can increase several-fold while maintaining a normal ratio of mucous and serous cells.[63,64]

The rate of submucosal gland secretion can be greatly increased by cholinergic, adrenergic, and peptidergic stimulation. Recent work shows that mucus is released in strands from submucosal glands, and that these strands help clear large particles from the airway surface.[65,66] The importance of submucosal glands to mucociliary clearance of large particles and to defense against bacterial infection is indicated by studies in pigs that lack submucosal glands due to targeted deletion of ectodysplasin and to the presence of airway disease in humans who lack glands due to spontaneous mutation of genes in the ectodysplasin signaling pathway.[67] Besides their roles in clearance and antimicrobial defense, submucosal glands provide a protected niche for myoepithelial stem cells at the base of serous acini that can repopulate the surface epithelium as well as the submucosal gland after severe airway injury.[68]

■ Mucociliary and Cough Clearance

Mucus rises in the trachea by ciliary beating, then normally leaves the lungs by passing through the vocal cords to enter the pharynx and be swallowed (Fig. 6-1A). The vocal cords are covered by squamous epithelium that cannot provide a propulsive surface, but the posterior commissure is covered by mucociliary epithelium and is ideally situated adjacent to the esophagus.

Approximately 30 mL of respiratory mucus is normally propelled out of the lungs daily, carrying inhaled particles and pathogens that are excreted in the gastrointestinal tract.[69] Notably, mucins are required to provide sufficient viscoelasticity for cilia to propel the mobile airway surface liquid layer against gravity because an isotonic salt solution slides downward rather than rising upward.[17]

The rate of mucociliary clearance can be measured in different animal species by a wide variety of techniques. In rodents, the clearance from the lungs of polystyrene beads instilled through the trachea or measurement of the movement of beads in excised tracheas have been commonly used.[26,28] In pigs, the movement of inhaled tantalum microdisks in central airways has been observed by computed tomographic imaging.[70] In human subjects, direct bronchoscopic observation of the movement of instilled particles and external imaging of the movement of radiolabeled particles (scintigraphy) have been used. From a practical standpoint, only the latter is performed commonly, as follows. Small, radiolabeled particles, such as sulfur colloid labeled with technicium-99m, are inhaled, followed by serial imaging with a planar gamma camera.[69,71] The movement of labeled particles from peripheral to central lung regions over the course of several hours is then measured. This technique is used for the evaluation of both disease pathophysiology and the efficacy of therapeutic interventions.[71] Mucus velocity is highest in the trachea and decreases in more distal airway generations.[69] Different techniques yield different velocities, but these center around a mucus velocity of ~5 mm per minute in the trachea of a healthy young adult.

Cough clearance provides an important backup mechanism when mucociliary clearance is impaired. The effectiveness of cough depends upon sufficient muscle strength, glottic function, and airway caliber to generate high-velocity airflow.[72] Mucus can then be mobilized by the resulting shear force, either by overcoming adhesive bonds between mucus and the epithelial surface or by fracturing mucus cohesive bonds, though both mechanisms depend heavily on mucus concentration.[73] In small airways, airflow velocity is not sufficient to generate adequate shear force to mobilize mucus, consistent with the persistence of mucus plugs in small airways for years on CT imaging.[74–77] As can be done for mucociliary clearance, the rate of cough clearance in central airways can be measured by scintigraphy using standardized protocols of controlled coughs.[71]

Effective mucociliary clearance depends upon a mucus layer of appropriate viscoelasticity, a periciliary layer of sufficient depth, and effective ciliary beating. When these components are interacting optimally, particles and pathogens suspended in the 10,000 liters of air that are inspired daily are cleared from the lungs with minimal impact on the underlying epithelium. However, failure of any of these components can lead to cascading dysfunction that causes symptoms and contributes to disease pathogenesis.

MUCOCILIARY DYSFUNCTION IN DISEASE

The principal symptoms of mucociliary dysfunction are dyspnea and cough. Dyspnea is caused by reduction of the total cross-sectional area of the conducting airways from mucus occlusion. This occurs most commonly from diffuse plugging of small airways but may also occur when a central airway becomes obstructed by mucus due to an underlying anatomic abnormality. Cough is caused by the stimulation of vagal afferents in the intrapulmonary airways or larynx and pharynx. Patients often infer that laryngopharyngeal stimulation, described as "a tickle in the throat," results from postnasal drip because they recognize that mucus descends from the nasopharynx by gravity but are unaware it also ascends from the lungs by ciliary action. Physical signs of impaired mucus clearance include cough, bronchial breath sounds, rhonchi, and wheezes. Radiographically, retained mucus may appear as localized atelectasis or linear and branched opacities. It is important to recognize the role of retained mucus in disease presentation so that symptoms can be relieved and its contribution to disease progression addressed.

■ Asthma

The central role of diffuse airway obstruction by luminal mucus in fatal asthma (Fig. 6-10) has been recognized by pathologists for more than 100 years and confirmed in multiple subsequent autopsy case series.[78,79] Mucus occlusion is particularly dangerous in asthma because smooth muscle contraction around the luminal plugs further constricts airflow. The principal underlying cause of mucus dysfunction in asthma is mucin overproduction. This is usually driven by allergic inflammation mediated by IL-13,[80] although IL-17 also can cause mucin overproduction and airway hyper-responsiveness.[81–83] IL-13 can increase the production of MUC5AC in human airway epithelial cells in vitro 100-fold,[30,31] and the production of MUC5AC in the lungs of mice in vivo 40-fold.[32] In contrast, the production of MUC5B increases minimally or may even decrease.[32,84]

Mucus plugs in asthma often have a rubbery quality, suggesting that the large quantities of mucins that are produced overwhelm the available airway surface liquid when they are suddenly secreted in response to inflammatory stimuli. This abnormality can occur despite the additional hydration provided by SLC26A9 and ClCa1-dependent CaCC activity that are coordinately upregulated with MUC5AC production by IL-13.[30,46] Additional contributors to abnormal rheologic properties of asthmatic mucus are a high concentration of plasma proteins resulting from increased microvessel density and permeability in the airway wall,[85,86] and the presence of granule, cytoplasmic, and nuclear macromolecules from eosinophils and other leukocytes.

Recent work using CT imaging reveals a high prevalence of mucus plugs in distal airways associated with eosinophilia and airflow obstruction.[74] Remarkably, these plugs can persist for many months. The therapeutic focus in addressing mucus dysfunction in asthma should be reducing mucin overproduction and plasma extravasation through use of anti-inflammatory drugs. Corticosteroids have been the mainstay of treatment, but immunotherapies directed at IgE, IL-13, IL-5, and other inflammatory mediators play increasing roles. Mucin overproduction in non-eosinophilic asthma remains poorly understood and with inadequate treatment options. Further discussion of the pathogenesis and therapy of asthma is found in Chapters 43–45.

■ Cystic Fibrosis

Complications from the impaired clearance of airway mucus dominate the clinical course of patients with cystic fibrosis (CF).[4,87,88] An autosomal recessive disorder, CF is caused by mutations in CFTR, a 180-kDa anion channel (see Chapter 48). CFTR is expressed throughout the conducting airways on the apical surface of secretory cells, and in proximal airways it is also expressed at a high level in ionocytes.[24] In submucosal glands, it is expressed in serous cells and ductal secretory cells[24,62] (Fig. 6-9).

More than 1900 pathogenic CFTR variants have been described. These mutations cause an imbalance between salt and water absorption mediated by the epithelial sodium channel (ENaC) and secretion mediated by CFTR (Fig. 6-11), resulting in insufficient airway surface liquid and the formation of excessively concentrated mucus.[89] Defective CFTR function also causes deficient bicarbonate secretion that results in impaired mucin unfolding and reduced activity of antimicrobial peptides secreted by airway epithelial cells.[90] It causes deficient secretion of thiocyanate, which is normally oxidized by lactoperoxidase to form isothiocyanate, an antimicrobial effector of the innate immune system that is variably reduced in CF.[91]

Retained luminal mucus is apparent pathologically in small airways and glandular ducts early in life.[59] Biophysical properties of mucus scale with the third power of mucin concentration,[4] so seemingly modest increases in mucin concentration in CF result in dramatic increases in mucus viscoelasticity and adhesivity that impair ciliary and cough clearance.[92] Unlike asthma, in which increased MUC5AC predominates, the expression of both secretory

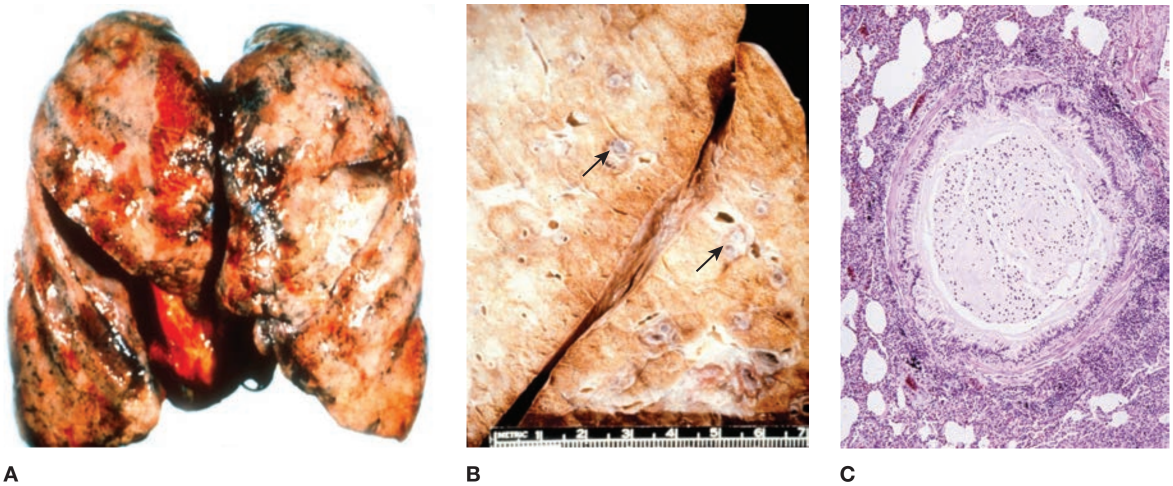

Figure 6-10 Airway obstruction by mucus in asthma. **A.** Lungs removed at autopsy from a patient who died from asthma. mucins, MUC5B and MUC5AC, is increased in the CF airway, driven by the inflammatory cytokine, IL-1β.[33] In addition, the presence of substantial amounts of DNA in CF mucus from necrotic neutrophils impairs ciliary clearance because the higher rigidity of DNA compared to mucins increases mucus viscosity even at low concentrations.[56] As disease progresses, the concentrated mucus layer draws water from the periciliary layer (Fig. 6-11), compressing cilia and making ciliary beating impossible.[13,16]

A porcine model has shown that tethered strands of mucus secreted by submucosal glands limits mucociliary clearance in the proximal airway.[93] These strands form because inadequate bicarbonate transport by mutant CFTR results in impaired mucin unfolding as it exits the gland duct.[6,8] Data from the newborn CF pig suggest that early defects in mucociliary clearance fail to clear inhaled bacteria even before the onset of airway inflammation.[94] This failure of mucociliary clearance results in airway colonization with bacteria and fungi, and paradoxically, the mucus gel layer and glandular secretions that evolved to protect the lungs from infection instead provide a protected environment for microbial growth.[4,87]

Aerosolized hypertonic saline solution, DNase, and antibiotics have become mainstays of CF therapy, while more recently, oral small molecule CFTR potentiators and correctors have had a dramatic effect in preventing disease progression.[1,4,87] Further discussion of the genetics, pathogenesis, and evolving therapy of CF is found in Chapter 48.

■ Primary Ciliary Dyskinesia and Other Motile Ciliopathies

Primary ciliary dyskinesia (PCD) is a rare, genetically heterogeneous disease with an estimated prevalence of 1 in 10,000–20,000 live-born children.[95] It typically presents early in life, with many affected children presenting within 24 hours of birth and requiring supplemental oxygen or mechanical ventilation for days or weeks.[96] Most patients with PCD have daily, year-round "wet" or productive cough.[96] Abnormal lung function develops early, and intrathoracic airway obstruction can worsen with increasing age.[97] In contrast to CF, cough clearance is relatively preserved in PCD, which partially compensates for defective ciliary clearance (Fig. 6-11). However, the lower airway is still chronically infected, and bronchiectasis is common with predilection for the right middle lobe and lingula.[98]

Upper airway involvement is common, manifested as daily, nonseasonal rhinosinusitis with watery nasal discharge that begins under 6 months of age.[96] Middle ear involvement is nearly universal, with chronic otitis media with effusion, often associated with conductive and sensorineural hearing loss.[99] Roughly half of all people with PCD have left-right laterality abnormalities, including *situs inversus totalis* and heterotaxy syndromes that can be associated with congenital heart disease.[100] Male and female subfertility are other non-respiratory complications, related to sperm dysmotility and ciliary dysfunction in the fallopian tubes, respectively.[101] Rarer manifestations of PCD include prenatal hydrocephalus and blindness due to *RPGR* gene mutations.[102] Patients with PCD also have a higher prevalence of pectus excavatum and scoliosis.[103]

Historically, the diagnosis of PCD has been challenging due to limitations of diagnostic tests, but newer tools have emerged during the past decade. Nevertheless, clinicians should only perform testing in patients who have a clinical phenotype compatible with the disease.[95] When combined with established clinical criteria, nasal nitric oxide (nNO) measurement is an effective screening tool in patients 5 years and older.[104] Reduced nNO concentrations alone are never sufficient to make the diagnosis, as individuals with CF or primary immunodeficiencies can also have lower nNO levels.[105]

Transmission electron microscopy evaluation of the ciliary axoneme for ultrastructural defects has been used for over four decades, although this diagnostic approach can no longer be considered the "gold standard" because people with PCD can have "normal" axonemal structure. Four ultrastructural patterns have consistently been described in PCD: outer dynein arm defects (Video 6-2); inner and

Figure 6-12 Genes linked to motile ciliopathies and their associated ultrastructural findings. IDA: inner dynein arm; MTD: microtubule disorganization; ODA: outer dynein arm. *(Reproduced with permission from Thomas W. Ferkol, MD.)*

outer dynein arm defects; microtubular disorganization with inner dynein arm defects; and radial spokes and central apparatus defects (Figs. 6-8 and 6-12). Inner dynein arm defects alone are often artefactual and rarely associated with disease, leading to false-positive diagnoses. Approximately 30% of persons with primary ciliary dyskinesia can have normal or only subtle changes in axonemal structure.[106] Adopted by many European centers, high-speed video microscopy has become a diagnostic approach, in which motile ciliary beat frequency and patterns in freshly excised or cultured ciliated epithelia are qualitatively assessed. However,[106] this technique has not been fully standardized.[107]

Advances in gene discovery have transformed genetic testing, and it has become a viable, first-line diagnostic tool. Several molecular diagnostic companies offer commercially available gene panels. Primary ciliary dyskinesia is primarily an autosomal-recessive disease, but autosomal-dominant and X-linked inheritance patterns have been described. To date, nearly 50 genes have been linked to disease,[108] most encoding proteins involved in ciliary structure, regulation, or assembly (Fig. 6-12). More than 70% of all patients tested have biallelic mutations within one of these genes. PCD exists as a clinical spectrum, and genotype-phenotype associations have emerged. For example, studies have shown that children who have *CCDC39* or *CCDC40* mutations have more rapid pulmonary function decline, whereas people with *RSPH1* defects tend to have milder lung disease.[109,110]

New understanding of cilia genetics has also revealed motile ciliopathies distinct from classical PCD. For instance, people with biallelic mutations in *CCNO* have clinical features similar to PCD but lack cilia on airway epithelial cell surface.[111] Single mutations in *FOXJ1*, a transcription factor that regulates cilia gene expression, similarly reduce the number of motile cilia, and are clinically associated with hydrocephalus, recurrent respiratory infections, and laterality defects.[112]

While the pathogenesis of PCD has classically been considered purely a problem of mucus propulsion (Fig. 6-11), sputum from patients with PCD is hyperconcentrated, similar to CF. This suggests that strain-induced release of ATP by ciliated cells, which normally induces fluid secretion by secretory cells, also is defective, promoting mucus plaque and plug formation.[4] Also similar to CF, the airway microbiota is dominated early in the course of disease by anaerobes, with subsequent acquisition of classic bronchiectatic pathogens such as *Staphylococcus aureus*, *Haemophilus influenzae*, and *Pseudomonas aeruginosa*.[4]

Finally, no treatment has been shown to correct cilia function in patients with PCD. Management has largely been extrapolated from those used to treat other diseases with abnormal mucociliary clearance, like CF, relying on airway clearance techniques and systemic antibiotics to mobilize secretions and reduce the bacterial burden of the lower respiratory tract, especially during acute respiratory exacerbations.[113] A recent, multicenter clinical trial showed that thrice-weekly azithromycin resulted in modest reduction in frequency of respiratory exacerbations.[114] Otherwise, the effectiveness of inhaled antimicrobials, hypertonic saline, and mucolytics has not been adequately studied thus far.

■ Chronic Obstructive Pulmonary Disease (COPD)

A role for mucus dysfunction in COPD has long been recognized in the syndrome of chronic bronchitis, defined as a persistent cough that produces sputum for at least 3 months per year in 2 consecutive years. The productive cough probably results from mucus overproduction in proximal airways due to surface epithelial mucous metaplasia and submucosal gland expansion, combined with ciliary dysfunction.[1,115] More recently a second role for mucus dysfunction in COPD has been recognized in the widespread obstruction of small airways identified in pathologic analysis of resected surgical specimens[116,117] and by CT scan.[77]

The extent of small airway mucus occlusion correlates with the degree of airflow obstruction, occurs even in patients with an emphysematous phenotype, and predicts longevity. These two mucus phenotypes in COPD—productive cough and airflow obstruction—correlate only weakly.[115] These findings suggest that individuals have differential susceptibility to the effects of cigarette smoke on different aspects of mucociliary clearance, as well as reflecting the independent roles of emphysema and small airway fibrosis in airflow obstruction in COPD. Notably, smokers with preserved pulmonary function who nonetheless have symptoms of productive cough and dyspnea experience exacerbations and activity limitation and show CT evidence of airway disease.[118]

A unifying feature of the pathogenesis of muco-obstructive lung diseases, including COPD, is that mucus hyperconcentration results in a failure of transport and in mucus adhesion to airway surfaces.[4] In the mucus of subjects with severe COPD, the concentration of MUC5AC is increased 10-fold and the concentration of MUC5B is increased 3-fold.[119]

Mucus overproduction and ciliary dysfunction both result from exposure to toxic products in cigarette smoke and environmental pollutants. Among these products, acrolein is a particularly potent inducer of MUC5AC production.[68] In addition to increased mucin production resulting from acute extracellular signaling, surface epithelial progenitors epigenetically committed to a mucous metaplastic phenotype overgrow the airways of COPD subjects.[120] In ciliated cells, cigarette smoke causes both structural and functional changes.[121] Besides these effects, cigarette smoke also decreases airway surface liquid by reducing CFTR function and increasing ENaC function.[122] As is the case in CF, impaired mucociliary clearance results in persistent airway infection, particularly with unencapsulated *Haemophilus influenzae*. Further discussion of the pathogenesis and therapy of COPD is found in Chapters 38–40.

■ Interstitial Lung Diseases

A link between mucus dysfunction and interstitial lung disease was not suspected until a genome-wide association study in 2011 found genetic linkage between a polymorphism in the MUC5B promoter and both familial interstitial pneumonia (FIP) and idiopathic pulmonary fibrosis (IPF). The promoter variant was found in 50% to 60% of individuals with FIP or IPF compared with 19% of unaffected individuals and increased the risk of disease 7-fold in heterozygotes and 21-fold in homozygotes.[35] Subsequent studies have extended the association to other idiopathic interstitial pneumonitides[123] and subclinical radiographic interstitial abnormalities.[124]

The presence of the promoter variant is associated with improved survival among patients with IPF,[125] presumably because it is a less severe driver of disease than other susceptibility genes. The promoter variant causes substantial overexpression of MUC5B (up to 20-fold), particularly in distal airspaces including honeycomb cysts. Whether disease ensues because of mucus dysfunction in the airway lumen, an epithelial stress response induced by the demands of synthesizing such a large and complex molecule, or some other mechanism is not yet known with certainty.

The risk allele is almost exclusively found in Caucasians, and there is evidence of positive selection, possibly by protection against a respiratory infection, consistent with the finding that a thicker mucus layer due to transgenic MUC5AC expression protects mice against challenge with influenza virus.[12] Further discussion of the pathogenesis and therapy of IPF is found in Chapter 54. The same MUC5B overexpressing risk allele is found in other interstitial lung diseases, including those associated with collagen-vascular diseases and hypersensitivity pneumonitis. These are further described in Chapters 52, 56, and 58.

■ Other Diseases

As discussed below, a variety of other diseases are characterized by alterations in mucociliary clearance, including idiopathic bronchiectasis, allergic bronchopulmonary aspergillosis, viral respiratory infections, panbronchiolitis, localized anatomic abnormalities of the airways, and disorders notable for retained mucus.

Idiopathic Bronchiectasis

Idiopathic bronchiectasis is a morphologic term that describes irreversibly dilated bronchi in the absence of a monogenic airway disease such as CF or PCD.[126,127] It is most commonly a sequela of lung infection but may also be associated with a defect in host defense such as immunoglobulin deficiency, or an inflammatory disorder such as a connective tissue disease. While it is most commonly identified by dilated bronchi on a CT scan, pathologic studies have identified severe small airway disease with bronchiolectasis, mucus plugging, and inflammation, consistent with the airflow impairment that is commonly observed.[4] Similar to CF and PCD, persistent airway infection and retained purulent secretions dominate the clinical course. In addition to antibiotic therapy during exacerbations, treatment with aerosolized hypertonic saline has been shown to improve lung function and quality of life.[128] In contrast, inhaled recombinant human DNase resulted in greater pulmonary function decline and more pulmonary exacerbations.[129] Bronchiectasis is covered in further depth in Chapter 51.

Allergic Bronchopulmonary Aspergillosis (ABPA)

ABPA is an inflammatory complication of chronic airway diseases, such as asthma and CF. It manifests clinically with wheezing and cough refractory to standard therapies, and with migratory radiographic lung infiltrates. It is characterized by an intense immunologic response to surface colonization with the fungus *Aspergillus fumigatus*, and florid MUC5AC overproduction induced by the persistent fungal infection leads to mucus impaction, atelectasis, and central bronchiectasis. The diagnosis is based on typical clinical features, elevated serum quantitative immunoglobulin E concentrations, positive skin test to *Aspergillus fumigatus*, and elevated in vitro *Aspergillus*-specific IgE and IgG levels or precipitins. ABPA is addressed in greater detail in Chapter 46.

Viral Respiratory Infections

Viral respiratory infections commonly lead to acute mucociliary dysfunction because of a combination of injury to ciliated cells, increased mucin production, and reduced airway surface liquid from ENaC activation by proteases.[4] Moreover, an acute respiratory viral infection can induce chronic lung disease through persistent overexpression of MUC5AC resulting from an IL-33—IL-13 signaling loop.[130] Viral infections of the respiratory tract are further discussed in Chapter 126 and in the previously noted chapters on asthma, COPD, and CF.

Panbronchiolitis

Panbronchiolitis is a syndrome of small airway inflammation and mucus obstruction that occurs predominantly in Asian subjects. It was reported to be associated in some cases with a polymorphism in the MUC5B promoter,[131] although a molecular mechanism of mucin gene dysfunction has not been identified. Further discussion of bronchiolitis can be found in Chapter 49.

Localized Anatomic Abnormalities

Localized anatomic abnormalities of the airways, such as the presence of a stricture, a surgical anastomosis, or a therapeutic stent, can result in mucus accumulation, obstruction, and atelectasis. It may be possible to remove the localized mucus accumulation by flexible or rigid bronchoscopy, and instillation of sodium bicarbonate solution may partially dissolve the mucus. Interventional bronchoscopy is reviewed in detail in Chapter 34.

Retained Mucus

Retained mucus is a common problem in intubated patients and those in whom lung mechanics are disrupted as a result of paralysis, immobilization, or surgery.[1] Atelectasis and pneumonia are frequent complications in such patients. Endotracheal and tracheostomy tubes impede generation of the high intrathoracic pressures required for effective cough clearance, endotracheal tubes block the path for normal mucociliary clearance through the posterior commissure of the glottis, and both types of tubes damage the mucosa and cause inflammation.[72] Effective endotracheal suctioning and subglottic secretion drainage can help prevent atelectasis and pneumonia, as discussed in Chapter 129 on Nosocomial Pneumonia, Including Ventilator-Associated Pneumonia.

In patients who have ineffective cough due to central nervous system injury or progressive neuromuscular disease, manually or mechanically assisted coughing is very helpful.[132,133] The roles and details of these techniques are further reviewed in Chapter 84. Postoperatively, early mobilization and deep breathing exercises or incentive spirometry are widely used despite the low quality of existing evidence of effectiveness.[134] These and other perioperative considerations are further discussed in Chapter 102.

■ Treatment

Therapies for mucus dysfunction can be classified into those that address mucin production, mucin secretion, mucin autophagy, mucus clearance, or airway infection.[1,135] Validated therapies in current use are described in the sections on specific diseases, above. Here, we review strategies in development.

Mucin Hyperproduction

Mucin hyperproduction is currently treated with agents designed to treat upstream signaling pathways, particularly in allergic asthma as described above. Additional signaling pathways under investigation are Notch and MAPK13.[135] Targeting mucin gene expression directly is under preclinical and clinical investigation. In view of the generally pathologic role of MUC5AC and the generally homeostatic role of MUC5B, strategies that selectively target MUC5AC production are attractive. Nonetheless, limited reduction of MUC5B overexpression in IPF or CF could also have therapeutic value. For both MUC5AC and MUC5B, careful assessment of their pathologic and protective roles will be required to optimize the therapeutic ratio of any intervention. Besides these pharmacologic strategies, ablation of mucous metaplastic surface epithelial cells by physical techniques including abrasion, cryospray, and pulsed electrical fields is under investigation.[136]

Mucin Secretion

Inhibiting mucin secretion may seem to be an obvious strategy to treat combined overproduction and secretion ("mucus hypersecretion"). However, it may not be possible to selectively target secretion of MUC5AC because it is packaged together with MUC5B in mucin granules. Nonetheless, the therapeutic value of selectively targeting stimulated mucin secretion, which causes airway occlusion, while leaving basal secretion intact, which mediates protective mucociliary clearance, has been demonstrated in mice.[42]

Autophagy

Recently, it was demonstrated that hyperproduced mucins can be degraded intracellularly by autophagy rather than being secreted.[45] Since autophagy can be activated by mTOR inhibition using drugs that are currently available, such as sirolimus and other rapamycin analogs, this presents another strategy that could reduce mucus hypersecretion.

Mucus Clearance

Treatments that promote mucus clearance include physical measures to remove retained secretions and pharmacologic agents to improve mucus rheology. Historically, physical measures were used extensively in CF, but perhaps less with the advent of highly effective CFTR potentiators and correctors. Physical measures remain in use to aid in the clearance of retained mucus as described above. Drugs that effectively improve mucus rheology in specific settings include inhaled dornase alfa, inhaled hypertonic saline solution, and systemic CFTR modulators, as indicated in the sections on specific diseases above. In addition, inhibitors of ENaC and potentiators of chloride channels other than CFTR are being developed.[135]

Mucolytics reduce mucus viscoelasticity by reducing disulfide bonds within and between mucin monomers. In the past, multiple trials of N-acetylcysteine failed to show benefit, probably reflecting its low reducing power and its cellular toxicity at therapeutic concentrations. However, these limitations are being overcome by multiple drugs in development that hold great promise.[135,137] Another strategy to reduce mucus viscoelasticity is by altering mucin ionic interactions.[138]

Antibiotics

For the treatment of infected airway mucus, a variety of inhaled, oral, and intravenous antibiotic regimens have been shown to have utility in specific situations, particularly in CF, PCD, COPD, and idiopathic bronchiectasis.[1,4]

CHAPTER 7

The Genetic Basis of Respiratory Disorders

Micheala A. Aldred

INTRODUCTION

The field of genetics and genomics continues to advance at an incredible pace since the completion of the Human Genome Project. Now, thanks to rapid advances in sequencing technology and bioinformatics, we have sequenced hundreds of thousands of genomes from around the world, uncovering great genetic diversity and challenging us to understand the biologic relevance. Sequencing the exome (the protein-coding parts of the genome) of a patient with an undiagnosed condition as part of their clinical evaluation is now commonplace, although distinguishing the causative genetic change from the myriad other nonpathogenic variants remains challenging. As other technologies develop, we increasingly look beyond our DNA sequence to understand the regulation and function of the resulting RNA (transcriptome) and proteins (proteome) it encodes, integrating these layers to understand complex biological networks in health and disease. Even beyond human genetics, genomic technologies are making an enormous impact on pulmonary disease. In 2020, as the COVID-19 pandemic emerged, the SARS-CoV-2 virus was quickly sequenced and shared, in the spirit of open science pioneered by the Human Genome Project. Existing bioinformatic networks that already tracked other pathogens, such as influenza, were repurposed to disseminate the latest knowledge on the evolution of the virus as it spread around the world. Knowing the sequence, understanding its relation to other coronaviruses, and modeling the structure of viral proteins has been pivotal in enabling the development of vaccine candidates in record time. Against this backdrop, this chapter on the genetics of lung diseases could easily be out of date before it is even in print. Thus, it does not seek to be encyclopedic, but rather gives the reader a grounding in the principles of human genetics, an overview of current knowledge in Mendelian lung diseases, and a summary of recent progress in understanding genetic factors contributing to common lung conditions. The chapter outlines some of the emerging roles of epigenetic modifications and aims to give a vision of where the field is moving, concluding with exciting advances and prospects for genetically targeted therapies.

PRINCIPLES OF HUMAN GENETICS

The sections below review the basics of genome organization, structure, and mutations; basic principles of inheritance; and mitochondrial mutations.

Genome Organization

The term *genome* refers to the genetic makeup of an organism (Table 7-1). Mammalian genomes are composed of deoxyribonucleic acid (DNA) and can be subdivided into a nuclear genome—DNA within the nucleus of each cell—and a separate circular genome housed within each mitochondrion. DNA has a double-helix structure. Each strand comprises four constituent bases—adenine (A), cytosine (C), guanine (G), and thymine (T)—that pair together, A with T and G with C. DNA needs to be replicated every time a cell divides. This strict base pairing ensures accurate copying of the DNA code.

The human genome is approximately 3.3 billion base pairs in size. This large amount of DNA is wound around proteins known as histones, then packaged into higher-order structures called chromosomes that can be visualized under a light microscope. Most cells of the body contain two copies of each chromosome, one inherited from each parent, and are termed *diploid*. Diploid cells contain 23 pairs of chromosomes. During meiosis, these pairs of chromosomes are separated, giving rise to oocytes and sperm that contain a single copy of each chromosome (termed *haploid*). Thus, fusion of two haploid gametes gives rise to a new diploid organism, preserving the correct copy number of DNA through the generations. Sex is determined by a pair of sex chromosomes, X and Y; females have two copies of the X chromosome, whereas males have one each of X and Y. The other 22 pairs of chromosomes are known as the autosomes. Genetic diseases are mainly caused by mutations in autosomal or X chromosome genes; the Y chromosome harbors only a few genes, and these are mainly involved in determining male characteristics.

Gene Structure

Only about 1% to 2% of the human genome actually encodes for proteins. The noncoding portion was originally considered to be junk DNA, but it is now increasingly clear that some of it has important regulatory functions. The protein-coding units are called genes. The DNA within a gene is first transcribed into ribonucleic acid (RNA). RNA has a similar base structure to DNA, but it is single stranded, it has a slightly different sugar backbone, and thymine (T) is replaced by uracil (U). Genes are typically divided into coding exons and intervening noncoding introns. The intronic sequences are spliced out of the initial RNA transcript to produce the mature messenger RNA (mRNA) molecule. Some genes have alternative splicing patterns that can give rise to slightly different variants ("isoforms") of the protein. The mRNA is then translated into protein by ribosomes. Ribosomes read the RNA code as a triplet of bases or "codon" and add the corresponding amino acid to the growing protein chain. There is some redundancy in the genetic code, and amino acids may be encoded by several different codons. Four codons have a special function: AUG encodes methionine and always marks the initiation site for protein translation, while UGA, UAG, and UAA are stop signals that lead to termination of translation. The DNA flanking the coding region of a gene is not translated but contains important regulatory elements, including the promoter region that regulates transcriptional activity.

Classes of Mutations

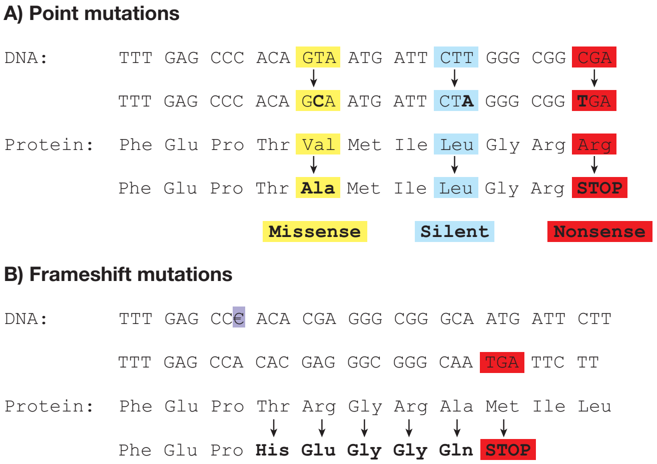
Alterations in the DNA sequence occur when there is an error in DNA replication prior to cell division or DNA damage occurs through environmental exposures such as UV radiation or tobacco smoke. Such mutations may affect a single base (known as a point mutation) or may involve the insertion or deletion of multiple bases. Cells have an extensive DNA repair mechanism that will correct most of these mutations, but any that escape may lead to a permanent change in the sequence that is propagated to daughter cells. Mutations in noncoding regions of the genome often have no detrimental effect, and over time they may become quite common in the population. Variants that are present at a frequency of greater than 1% are known as polymorphisms and have been widely used in genetic mapping studies. Thus, the two copies of a gene in any individual are subtly different at the DNA sequence level. These variant forms are known as "alleles." However, mutations that occur in the introns of genes may lead to disease, especially if they disrupt the highly conserved splicing signals immediately flanking an exon.

TABLE 7-1 Glossary of Genetic Terms

Genome	The complete genetic makeup of an organism, including all coding and noncoding DNA
Gene	A discrete protein-coding unit within the genome. Genes are typically subdivided into exons (blocks of protein-coding DNA), introns (intervening noncoding DNA), and flanking regulatory regions
Exome	The entire sequence of all exons within the genome
Somatic	Relating to any cell of the body other than the germ cells. Mutations in somatic cells cannot be passed on to the next generation
Chromosome	A higher-order structure into which DNA is packaged. Humans have 23 pairs of chromosomes, 22 autosomes, and a pair of sex chromosomes, X and Y, that determine sex
Telomere	The cap at the ends of each chromosome, composed of hundreds of copies of the repeat sequence TTAGGG
Diploid	Containing a full complement of 23 chromosome pairs. All normal somatic cells are diploid
Haploid	Having only a single copy of each chromosome. Mature gametes are haploid, ensuring that a new zygote has the correct chromosome complement
Aneuploid	Cells that have a nondiploid number of chromosomes due to gain or loss of one or more chromosomes during cell division. Aneuploidy commonly occurs in cancer cells, which may become highly abnormal as the tumor progresses
Mutation	Strictly, any change that occurs in the DNA sequence; in relation to genetic diseases, the term is mainly used to refer to changes that have a deleterious clinical effect
Polymorphism	A genetic variant present at a frequency of at least 1% in a given population, often used synonymously with mutations that have no adverse effect
SNP	Single nucleotide polymorphism: a polymorphism resulting from a single DNA base substitution
Allele	Referring to a specific version of a gene, often used to distinguish between the copies inherited from each parent, or between wild-type and mutant copies
Heterozygote	An individual with one wild-type allele and one variant
Homozygous	An individual with two copies of the same variant allele. In autosomal recessive diseases where an individual inherits two different mutations, one from each parent, the term "compound heterozygote" is used
Genotype	The genetic sequence of the two alleles at a particular gene location
Phenotype	The clinical manifestation of genetic change
Dominant	A mutation that exerts a phenotypic effect in heterozygous form
Recessive	A mutation that is masked by the wild-type allele in a heterozygote and only results in a phenotype when wild-type function is lost
Penetrance	The likelihood that an individual with a mutation will develop clinical disease
Heterogeneity, allelic	The presence of different pathogenic mutations in same gene across different individuals. Most genetic diseases show allelic heterogeneity, unless they are caused by gain of an abnormal function that is only conferred by one specific mutation (e.g., sickle cell disease)
Heterogeneity, genetic	Diseases for which a mutation in one of several different genes can lead to the same clinical phenotype
Heritability	The proportion of trait variance that can be attributed to genetic factors versus the environment
Haplotype/haplogroup	A specific combination of SNPs on a contiguous piece of DNA. *Haplotype* is used when defining the arrangement of SNPs on an individual chromosome; *haplogroup* refers to groups of ancestrally related variants in mitochondrial genome
Genetic anticipation	A phenomenon in which the age of onset of an autosomal dominant disease becomes earlier with each successive generation. It is most often observed in a group of neuromuscular diseases caused by a unique class of DNA-repeat mutations, but also occurs in familial pulmonary fibrosis associated with telomerase mutations
Imprinting	Epigenetic silencing of an allele based on its parental origin. Relatively few genes are imprinted, but those that are give rise to unusual patterns of inheritance, as the mutation is masked when present on the silenced allele

Within the coding region of a gene, the consequence of a point mutation depends on whether it alters the genetic code (Fig. 7-1). Most redundancy lies in the third base of the codon, so, for example, a change from GGG to any of GGA, GGC, or GGU still encodes glycine and would not change the sequence of the protein. Such changes are usually silent and may become common polymorphisms. Mutations that lead to an amino acid substitution, for example UGU (cysteine) to UAU (tyrosine), are known as missense mutations. Their effect on protein function depends much on the specific structure and function of that protein. In general, missense mutations in regions that are functionally critical, such as the catalytic domain of an enzyme, will be highly deleterious. These regions are often highly conserved across species, indicating that mutations have not been tolerated during evolution. Missense mutations that affect residues important in secondary structure and protein folding also are likely to have adverse effects, whereas mutations in linker regions may be less critical. Thus, interpreting the consequences of genetic changes requires an in-depth knowledge of the protein concerned.

Mutations that lead to premature truncation of a protein are highly likely to be pathogenic and are a major cause of inherited diseases. Several different types of mutation can lead to premature protein truncation. Nonsense mutations result from a single base change that introduces a stop codon earlier than the natural translation endpoint, for example, AGA (arginine) to UGA (stop). Small insertions and deletions also can introduce premature stop codons because if the number of bases added or lost is not a multiple of three, the reading frame for the triplet codon is offset and it is read incorrectly. This is known as a frameshift mutation



A) Point mutations
DNA: TTT GAG CCC ACA GTA ATG ATT CTT GGG CGG CGA
TTT GAG CCC ACA GCA ATG ATT CTA GGG CGG TGA
Protein: Phe Glu Pro Thr Val Met Ile Leu Gly Arg Arg
Phe Glu Pro Thr Ala Met Ile Leu Gly Arg STOP
Missense
Silent
Nonsense
B) Frameshift mutations
DNA: TTT GAG CCG ACA CGA GGG CGG GCA ATG ATT CTT
TTT GAG CCA CAC GAG GGC GGG CAA TGA TTC TT
Protein: Phe Glu Pro Thr Arg Gly Arg Ala Met Ile Leu
Phe Glu Pro His Glu Gly Gly Gln STOP

Figure 7-1 Classes of genetic mutations. **A.** Single base changes within an exon may lead to premature protein truncation (nonsense mutation, shaded in red), or an amino acid substitution (missense mutation, yellow), or there may be no change due to redundancy in the genetic code (silent, blue). **B.** Insertions or deletions lead to frameshift mutations if the number of bases involved is not divisible by three. This almost invariably leads to premature protein truncation downstream of the mutation site. In this example, deletion of a single G (shaded gray) changes the amino acid sequence and quickly ends with a STOP codon.

(Fig. 7-1). Splice-site mutations can lead to retention of an intron, which does not normally code for a protein and, therefore, often contains a stop codon. Alternatively, splice-site mutations can lead to exon skipping and again, if the size of the missing exon is not a multiple of three bases, this leads to a downstream frameshift, in addition to losing a whole exon of sequence. The presence of a premature stop codon often triggers a process known as nonsense-mediated mRNA decay (NMD), which leads to degradation of the nonsense-containing mRNA transcript, preventing translation of a truncated protein. This protects the cell from potentially adverse effects of an abnormal protein product. The mechanisms underlying NMD are not fully understood, and some transcripts are degraded more efficiently than others. Nonsense mutations in the last exon of a gene do not trigger NMD, due to their proximity to the natural stop codon, whereas mutations in the first exon, close to the translation initiation codon, may lead to re-initiation at a downstream ATG site.

The last major class of mutation is gene rearrangements, large deletions, or duplications that affect one or more exons. These mutations can be missed by sequence-based methods of DNA analysis and require specialized methods that measure the copy number of DNA across the gene. They typically lead to major disruption of the gene structure, and any protein that may be produced is likely to be nonfunctional.

■ Modes of Inheritance

The pattern of inheritance of a genetic disease within a family is determined by the location of the mutation—on an autosome, the X-chromosome, or in the mitochondrial genome—and whether a clinical effect (phenotype) is evident when only one copy of the gene is mutated. When mutation of a single allele is sufficient to cause disease, it is known as dominant because the mutation is sufficient to overcome the positive effect of the remaining wild-type allele. Genes that are affected by dominant mutations are typically very sensitive to the 50% reduction in gene dosage that results from inactivating one allele. Alternatively, the mutation may cause an abnormal gain of function, or create an abnormal protein that in turn interferes with the function of the wild-type protein, an effect known as dominant negative. In contrast, recessive mutations have no detrimental effect when only one allele is mutated. The remaining wild-type allele is sufficient to maintain normal gene function, and a clinical phenotype is apparent only when both alleles are inactivated, and the gene function is completely lost. Individuals with a personal or family history of genetic disease should be offered genetic counseling to help them understand their risks and options, and to facilitate appropriate genetic testing.

Autosomal Dominant

Autosomal dominant mutations result in a strong pattern of disease in each generation of a family (Fig. 7-2A). An individual with such a mutation has a 50% chance of passing the disease on to each of their children. The hallmarks of autosomal dominant inheritance are approximately equal proportions of males and females affected by the disease and the presence of male-to-male transmission. However, several factors can complicate this model. Some dominant diseases may skip a generation, due to reduced penetrance (Fig. 7-2B). The penetrance of a mutation is defined as the likelihood that someone with the mutation actually develops the disease. If the penetrance is less than 100%, then an individual who inherits the mutation may escape the disease themselves, while still being at 50% risk of passing it on to their children. Independently, the gender ratio may be skewed by environmental and/or genetic modifying factors. The most extreme example is inherited diseases affecting sex-specific organs. For example, ovarian cancer may be inherited in an autosomal dominant manner, but only females with the mutation actually develop the disease.

Autosomal Recessive

The pattern of inheritance of autosomal recessive diseases is quite different. Individuals with a single copy of the mutation are known as carriers or heterozygotes. Since there is no clinical effect, such individuals are usually unaware of their status. However, when both parents are carriers, each has a 50% chance of passing on the mutation, meaning there is a 25% chance that a child will inherit two copies of the mutation and be affected by the disease. Consequently, autosomal recessive diseases often appear "out of the blue" in a family with no previous history of the condition (Fig. 7-2C). The incidence of recessive diseases largely depends on the heterozygote frequency in the population, but the risk increases in consanguineous families.

X-Linked Inheritance

X-linked diseases are caused by mutations in genes on the X-chromosome. Most are recessive, but the different sex-chromosome constitution between females and males, XX versus XY, leads to a unique pattern of inheritance. Males who inherit an X-linked mutation have no wild-type allele on the Y-chromosome to mask its effect, and consequently they develop the disease. Female carriers are generally unaffected, as for autosomal recessive diseases. Thus X-linked diseases are passed through the female line and typically affect only males (Fig. 7-2D). A female carrier has a 50% chance of an affected son. Importantly, males cannot pass the mutation to their sons, so evidence of male-to-male transmission rules out X-linked inheritance; however, all their daughters will be carriers.

Females only have a single X-chromosome active in any given cell, due to a process of X-inactivation in early embryonic development that adjusts the dosage of X-linked genes to be the same as in males. If X-inactivation is random, approximately half of cells in a carrier will express the wild-type allele and half express the mutation, meaning that female carriers usually have no phenotype or are only mildly affected. However, if X-inactivation is highly skewed toward expression of the mutant allele, then female carriers may be as severely affected as males. Rarely, X-linked mutations may be dominant, meaning that all females who inherit the mutation will be affected. Such mutations are often lethal in males. Examples of X-linked recessive conditions that affect the lung include X-linked agammaglobulinemia, an immunodeficiency that can lead to chronic lung disease, and X-linked severe combined immunodeficiency caused by mutations in the *IL2RG* gene that encodes a subunit of the receptor for multiple interleukins.

■ Mitochondrial Mutations

The mitochondrial genome is a small circular molecule, approximately 16,500 bases long. It encodes some of the proteins required for oxidative phosphorylation and electron transport, together with multiple transfer RNAs and ribosomal RNAs. Mutations in mitochondrial genes adversely affect energy production and thus the clinical consequences are greatest in tissues with high-energy requirements, such as heart, brain, and skeletal muscle.

Two characteristics make the inheritance of mitochondrial gene mutations unique. First, mitochondria are almost exclusively transmitted through the maternal lineage; sperm only have mitochondria in the tail for motility and do not enter the oocyte at fertilization. Thus, the pattern of inheritance within a family is similar to X-linked inheritance, with no male-to-male transmission, but it differs in that females and males are equally likely to be affected (Fig. 7-2E). In theory, all children born to an affected mother would

Figure 7-2 Patterns of inheritance of genetic diseases. **A.** Autosomal dominant inheritance is characterized by the presence of disease in every generation, equal gender distribution, and male-to-male transmission. **B.** When an autosomal dominant disease has reduced penetrance, it may skip a generation. **C.** Autosomal recessive disease suddenly appears in the family when both parents are heterozygous mutation carriers. **D.** X-linked recessive diseases are transmitted by carrier females but in general, only males are affected. Male-to-male transmission is impossible. **E.** Mitochondrial diseases are transmitted through the female lineage and can potentially affect all children born to an affected mother. Key: *Squares* denote males; *circles*, females; *solid symbols* denote individuals affected by the disease; *circles with a dot in the center* denote obligate carriers of an X-linked condition.

inherit the mutation and develop the disease. However, there are many copies of the mitochondrial genome per cell, and each cell has a mixture of wild-type and mutant mitochondria (*heteroplasmy*). The segregation of these mitochondria during cell division is random, so, by chance, an oocyte may have a high or low number of mitochondria carrying the mutation. This random drift continues throughout embryonic development and beyond, generating considerable variability in the severity of disease and the tissues that are affected, even among individuals in the same family.

Pulmonary involvement is not a major feature of most mitochondrial diseases, but several case reports link pulmonary hypertension with mutation in mitochondrial genes or a nuclear-encoded mitochondrial protein.[1–11] Pulmonary complications of mitochondrial disease are most likely to present as part of a multiorgan syndrome that may also include cardiac and/or skeletal myopathy, neuropathy, retinopathy, renal problems, or metabolic abnormalities.

Another fascinating property of the mitochondrial genome is its high degree of polymorphic variation. Clusters of variants, or "haplogroups," have been used to plot early human migration patterns across the globe. As new variants arose, they were propagated to offspring in the immediate geographic area but were not present in other populations that had already migrated to different regions. Some of these variants confer subtle functional differences and may have been selectively enriched by helping adaptation to a new environment. They may also modulate risk of disease, particularly for conditions where there is oxidative stress. Data concerning lung diseases are currently limited, but associations with different haplogroups and or mitochondrial DNA copy number have been reported for atopy and asthma, chronic obstructive pulmonary disease (COPD), high-altitude pulmonary edema, pulmonary hypertension, and lung cancer risk.[12–19]

SOMATIC MUTATIONS AND CANCER

Not all the genetic changes that contribute to disease are inherited. This is particularly true in cancer where, although there may be an inherited predisposition, most genetic changes are somatic and confined to the tumor itself. A later chapter is devoted to the molecular basis of lung cancer, so here we will briefly review the types of somatic changes observed in cancer cells and their relevance to benign lung conditions.

Two major classes of genes may be mutated in cancer: oncogenes and tumor suppressor genes. Oncogenes promote tumorigenesis when they are expressed at an abnormally high level or are inappropriately expressed in tissues where the gene should normally be silent. This may occur due to amplification (extra copies) of the gene, overactivation by upstream transcription factors, a chromosome rearrangement that brings the gene under the control of a strong promoter, or loss of DNA methylation as described in the following section on epigenetics. Alternatively, the gene may be mutated in a way that gives the protein a novel gain of function—for example, mutation of a ligand-dependent receptor such that, once activated, it cannot be switched off and continues to signal in the absence of the ligand. These types of oncogenic mutations are usually dominant missense mutations at specific amino acid sites within the protein.

Tumor suppressor genes (TSGs) are like the brakes on the cell; they control cell growth, differentiation, and apoptosis. When their function is lost, the cell proliferates uncontrollably or evades programmed cell death. TSGs are predominantly inactivated by nonsense and frameshift mutations, large gene deletions, or loss of an entire chromosome. They may also be silenced by hypermethylation of their promoter, as described in the next section. In contrast to oncogenes, TSG mutations are often recessive at the cellular level and both copies of the gene must be inactivated before the full cancer-promoting effect is seen. Both mutations may occur as somatic changes in the cell that initiates the cancer, or the first mutation may be inherited, predisposing the individual to the risk of cancer, a model that was first proposed by Alfred Knudson.[20]

As tumors proliferate, their genome may become highly disorganized. Abnormal segregation of the chromosomes during mitosis can lead to aneuploidy, with gains and/or losses of entire chromosomes. There may also be translocations, where segments of different chromosomes are inappropriately joined together, and localized deletions or duplications of large segments of DNA. Such large rearrangements will clearly affect many different genes and can contribute to the activation of oncogenes and/or loss of TSG function.

The study of somatic mutations requires tissue from the affected area and ideally entails comparison with normal tissue from the same patient, as well as normal tissue from unrelated controls. Due to the difficulty of obtaining such tissues for benign lung diseases, somatic changes have mainly been studied in the context of cancer, but the same approach has recently been applied to pulmonary arterial hypertension (PAH). In addition, somatic epigenetic changes described below are common both in cancer and in several chronic lung diseases, emphasizing the importance of acquiring tissue from the site of disease when this is ethically possible.

EPIGENETICS

The term *epigenetics* refers to factors that influence gene expression without altering the underlying base sequence. Both DNA and histones, the proteins around which DNA is wound, may be epigenetically modified. These changes are usually reversible and play important roles in regulating gene expression and genome stability.

■ DNA and Histone Modifications

The most common DNA modification is methylation of cytosine residues. The promoters of many genes contain a CpG island, a region with a high density of CG dinucleotides. Methylation of CpG sites in these islands leads to a closed chromatin conformation that makes the DNA inaccessible to transcription factors, turning off expression of the gene. Conversely, when most of the cytosines are unmethylated, the DNA is open and actively transcribed. DNA methylation, therefore, plays a critical role in regulating tissue-specific patterns of gene expression. Patterns of DNA methylation are controlled by DNA methyltransferases (DNMTs). DNMT3A and 3B are responsible for de novo methylation of residues that were previously unmethylated. Established patterns of methylation are then maintained by DNMT1. Further fine tuning of gene regulation comes through methylation and acetylation of histones. Acetylation mainly occurs on lysine residues and relaxes the interaction between histone and DNA, leading to increased gene transcription. Deacetylation reverses this and leads to a more tightly closed chromatin conformation. Histone acetylation patterns are controlled by histone acetyltransferases (HATs) and deacetylases (HDACs).

Within noncoding regions of the genome, DNA methylation and chromatin condensation act to suppress repetitive elements that could otherwise recombine and cause structural alterations. In cancer, there is often a global loss of methylation, which can lead to activation of mobile and repetitive elements, predisposing to the genomic instability that is the hallmark of many cancers. Loss of methylation at gene promoters can also activate oncogenes that in turn accelerate the growth of the tumor. At the same time, there may be hypermethylation of specific gene promoters, causing loss of expression of TSGs.

It is increasingly clear that more subtle epigenetic changes likely contribute to variation in normal lung function and lung diseases, including idiopathic pulmonary fibrosis (IPF), pulmonary hypertension, and COPD.[21–24] Unlike the DNA sequence, epigenetic modifications can change dynamically with age and are influenced by dietary factors such as folate intake. There is also mounting evidence that airborne pollutants, such as small diesel particulates and tobacco smoke, can directly mediate epigenetic changes.[25,26] Thus, the lung may be particularly susceptible to epigenetic changes caused by repeated exposure to these environmental modulators, influencing disease susceptibility and severity.[27–29] Importantly, though, some adverse epigenetic changes are reversible with time, for example, smoking-induced changes in DNA methylation gradually revert after quitting.[30] Also, the anti-inflammatory action of corticosteroids is, in part, epigenetic, recruiting HDAC2 to the site of acetylated (activated) inflammatory genes.[31] Characterizing the role of epigenetics in lung disease is challenging because it requires access to affected and control lung tissues. It may also be difficult to distinguish which changes are causative of disease and not just a reaction to the disease state. However, considerable progress has already been made under the auspices of the NIH Roadmap Epigenomics Consortium and other focused research initiatives.

■ Noncoding RNAs

Noncoding RNAs can directly regulate gene expression at the RNA level without being translated into a protein product. The best characterized family is the microRNAs (miRs), first studied in plants but now also recognized to be important throughout the animal kingdom. Primary miR transcripts are transcribed in the same manner as regular protein-coding genes. In some cases, the miR gene may be within an intron of a protein-coding gene and is controlled by the promoter of the "parent" gene. In other cases, miRs may be encoded as separate genes, individually or in a cluster, with their own promoter. The primary miR transcript is then processed into a pre-miR, about 70 to 80 nucleotides in length (Fig. 7-3). The ends of the pre-miR are highly homologous, causing the molecule to loop back on itself in a hairpin-like conformation. This double-stranded RNA structure is then exported from the nucleus into the cytosol, where it is cleaved by the enzyme Dicer into a mature single-stranded miR, approximately 18 to 22 nucleotides long (Fig. 7-3). The mature miR negatively regulates gene expression by binding to the 3′-untranslated region of its target mRNA, which either leads to degradation of the mRNA or inhibits protein synthesis. The seed sequence that initiates binding between the miR and its mRNA target is very short, typically around seven nucleotides, and does not require perfect base pairing. As a consequence, a single miR can potentially target tens or even hundreds of genes.

miRs have been widely studied in cancer, and several, such as miR-21, have been dubbed "oncomiRs" because their overexpression promotes tumorigenesis by downregulating tumor suppressor pathways.[32–35] In comparison, relatively little is known about the role of miRs in benign lung diseases. However, it is now an intense area of research and recent data highlight important roles in IPF and PAH, as detailed in the disease-specific sections that follow. The miR pathway is often considered to be an epigenetic mechanism, yet it can be influenced by changes in DNA sequence, either through mutation affecting the miR gene itself, or through mutations and polymorphisms that alter the seed sequence in the mRNA target.

Another major class of noncoding RNAs is the long noncoding (lnc) RNAs, greater than 200 bases long. lncRNA transcripts can be thousands of bases in length and, unlike miRs, they may be encoded

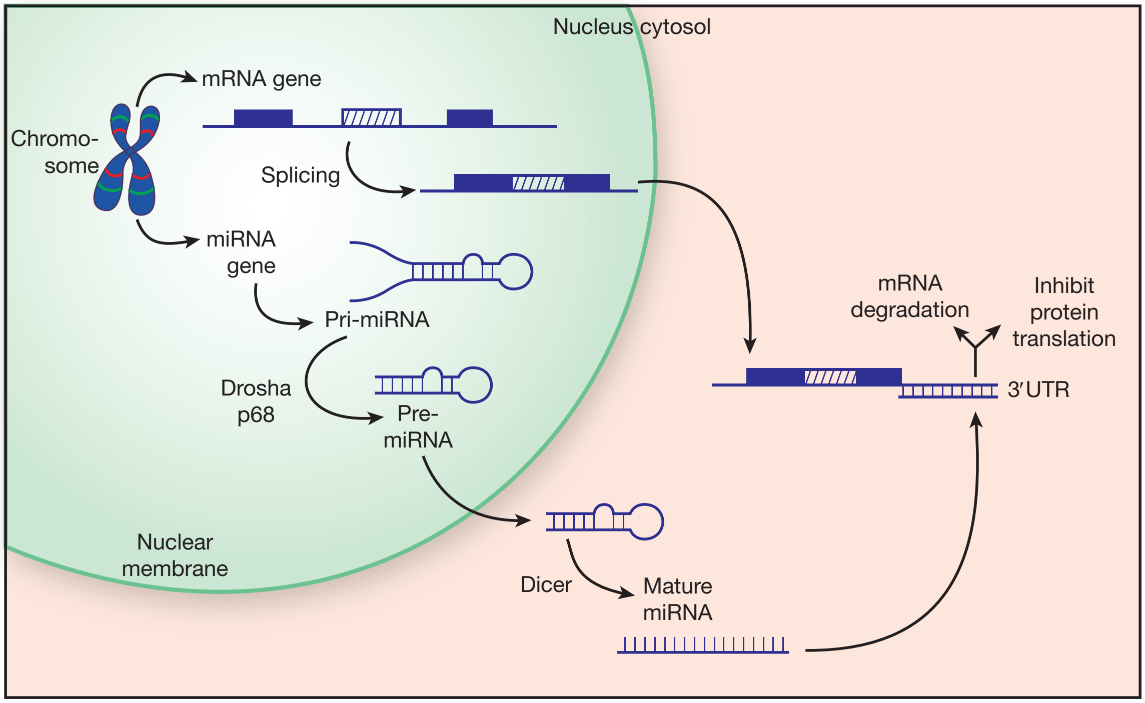

Figure 7-3 microRNA biogenesis. microRNAs that are encoded by independent genes are transcribed by RNA polymerases (mainly RNA pol II) into a primary miRNA transcript with a 5′-cap and 3′-polyadenylation. The primary miRNA molecule is cleaved by a protein complex, including Drosha and p68, into a double-strand hairpin RNA known as the pre-miRNA. For a subset of microRNAs, recruitment to the p68-Drosha complex is stimulated by activation of the bone morphogenetic protein and transforming growth factor-beta pathways,[85,86] a process that is disrupted by some mutations that cause pulmonary arterial hypertension.[68] Alternatively, some miRNA genes are embedded within the introns of mRNA genes, in which case they are transcribed along with the host gene and the pre-miRNA is generated during mRNA splicing. The pre-miRNA is then exported to the cytosol, where the Dicer complex converts it to the mature single-stranded miRNA molecule. Mature microRNAs negatively regulate expression of their target genes by binding to the 3′-untranslated region of the mRNAs, which either leads to degradation of the mRNA or blocks protein translation.

TABLE 7-2 Mendelian Inherited Lung Diseases

Disease	OMIM	Mode of Inheritance	Gene(s)	Chromosome	Comments
Cystic fibrosis	219700	Autosomal recessive	*CFTR*	7	ΔF508 accounts for ~75% of mutations; many other mutations described at a frequency of 5% or less
Alpha-1 antitrypsin deficiency	613490	Autosomal recessive	*SERPINA1*	14	Z allele (E342K) associated with severe disease, S allele (E264V) is intermediate
Sickle cell disease	603903	Autosomal recessive	*HBB*	11	Predominantly caused by a single mutation, E6V, which leads to an abnormal hemoglobin molecule (HbS)
Pulmonary arterial hypertension	178600	Autosomal dominant, reduced penetrance	*BMPR2* *SMAD9* *ACVRL1* *ENG* *CAV1*	2 13 12 9 7	6% to 10% of patients have a family history and an additional 15% to 20% of patients with sporadic idiopathic disease carry a mutation in one of these genes. *BMPR2* mutations account for about 80% of all families and more than 200 different mutations have been described. Several more genes have recently been identified by whole genome sequencing, as referenced in the text
Idiopathic/familial pulmonary fibrosis	614742 614743 178500 610913	Autosomal dominant, variable penetrance	*TERT* *TERC* *SFTPA2* *SFTPC*	5 3 10 8	Mutations in *TERT* or *TERC* lead to shortened telomeres. The severity of disease is inversely correlated with telomere length, and the age of onset decreases with each succeeding generation (genetic anticipation)
Surfactant metabolism dysfunction	265120 610921 614370 300770	Autosomal recessive X-linked	*SFTPB* *ABCA3* *CSF2RB* *CSF2RA*	2 16 22 X	Disease presentation can range from severe respiratory distress in neonates, through childhood or adult-onset interstitial lung disease. *SFTPC* mutations, listed above under IPF, can also lead to neonatal or childhood surfactant metabolism dysfunction
Alveolar capillary dysplasia	265380	Usually de novo	*FOXF1*	16	Caused by de novo heterozygous mutations or deletions of maternal origin; gene is imprinted; occasionally transmitted as a dominant trait by an unaffected mother
Primary ciliary dyskinesia	Multiple	Autosomal recessive	Multiple	Multiple	Highly heterogeneous disorder with at least 15 different genetic loci
Agammaglobulinemia	300300	X-linked	*BTK*	X	Rare B-cell disorder; recurrent respiratory tract infections
Severe combined immunodeficiency	300400	X-linked	*IL2RG*	X	Rare, affects at least two immune cell types; more severe than agammaglobulinemia; also several autosomal recessive forms

OMIM, Online Mendelian Inheritance in Man; http://omim.org/.

by large multiexon genes that undergo splicing in the same manner as most protein-coding genes. Well-known examples of lncRNAs are *XIST*, which coats the inactive X-chromosome in female cells, and *TERC*, part of the telomerase complex that maintains the ends of the chromosomes (telomeres). Currently, relatively little is known about the role of lncRNAs in human disease, the notable exception being *TERC* mutations, one of several causes of IPF described below.

INHERITED LUNG DISEASES

This section provides an overview of the genetic basis of inherited conditions that include lung disease as a major component (Table 7-2). These brief summaries cannot provide exhaustive reviews of current knowledge, but the reader is referred to entries in Online Mendelian Inheritance in Man (OMIM) and other web resources listed at the end of this chapter for in-depth information.

■ Cystic Fibrosis

Cystic fibrosis (CF; OMIM 219700) is the most common autosomal recessive disorder in Northern European Caucasians, with a carrier frequency of 1 in 20 to 1 in 25. It is caused by mutations in the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene on chromosome 7, which encodes a transmembrane channel protein important for chloride transport[36] (see Chapter 48). The most common mutation in Northern Europeans, accounting for about 75% of all CFTR mutations, is a deletion of three base pairs of DNA encoding phenylalanine at codon 508, denoted F508del. The frequencies of other mutations are all much lower, each accounting for less than 5% of the total. Thus, approximately 56% of individuals with CF are homozygous for F508del, and the majority of others are compound heterozygotes for two different mutations. In Southern Europeans, F508del is somewhat less common, and the mutation spectrum is markedly different in the Ashkenazi Jewish population. Many countries now perform newborn screening for the most common CF mutations, enabling early diagnosis and treatment.

CF mutations can be subdivided into several categories, based on their molecular consequences.[37] Class I mutations, including most nonsense, frameshift, and splice-site mutations and large gene deletions, result in loss of CFTR protein. Class II mutations encode stable proteins that are abnormally processed, leading to retention of the mutant protein in the endoplasmic reticulum. F508del is an example of a class II mutation. Class III and IV mutations localize correctly to the membrane but they either fail to activate or are inefficient at transporting chloride ions. Class V mutations reduce the rate of CFTR synthesis. Some of these mutations retain a degree of residual function and can mitigate the severity of clinical phenotype.[37,38] Understanding the molecular consequences of these different mutations has been instrumental to developing new therapeutic approaches that seek to correct these defects, as described in the concluding section of this chapter.

Most genetic diseases show variability in the extent and severity of clinical disease, even for individuals with identical mutations. Just as common SNPs may confer risk or protection for common disease, they may also act as genetic modifiers in Mendelian traits. CF is a multisystem disease and with a large enough cohort of patients, it has been possible to identify polymorphisms that modify different aspects of the disease, including pulmonary function (FEV_1), bacterial colonization, meconium ileus, and diabetes.[39,40] One particularly interesting polymorphism involves a run of thymine residues in intron 8 of CFTR, commonly present as 9T, 7T, or 5T alleles. These bases are just upstream of exon 9 of the gene and are part of an important signal to regulate mRNA splicing. The shorter alleles splice less efficiently; in particular, the 5T allele can lead to abnormal splicing that excludes exon 9 from a proportion of the transcripts. Since some full-length CFTR is still made, this is not a severe CF mutation. However, it can lead to a partial phenotype in combination with other mutations and is, therefore, an intragenic modifier. Embryonic development of the vas deferens in males is especially sensitive to the amount of CFTR protein, and the 5T allele can contribute to congenital bilateral absence of the vas deferens, even in individuals with little or no lung disease.[41]

■ Alpha-1 Antitrypsin Deficiency

Alpha-1 antitrypsin deficiency (AATD; OMIM 613490) is an autosomal recessive disease caused by mutations in the *SERPINA1* gene on chromosome 14, which encodes the protease inhibitor alpha-1 antitrypsin (AAT) (see Chapter 39). AATD was one of the earliest genetic diseases to be understood at the molecular level, since the variant alleles could be identified by protein gel electrophoresis (isoelectric focusing) before the advent of DNA-based genetic testing. Consequently, the alleles are denoted by letters assigned for their relative position on the gel. The wild-type allele is designated M. The most common deficiency allele is Z, a missense mutation that changes glutamic acid to lysine at codon 342 (E342K). Its frequency is highest in Northern European populations.

AATD is likely underdiagnosed, and the true prevalence may be higher than CF in some countries.[42–44] ZZ homozygotes have low plasma AAT concentrations and are at highest risk for developing lung disease. Accumulation of the mutant protein in the liver can also lead to liver damage. The other most common allele, denoted S (amino acid change E264V), is intermediate in respect to both the level of AAT and disease risk. It is highly prevalent in Southern European populations, with frequencies of 15% to 20% in Spain and Portugal.[44] Clinically, the S allele is of greatest concern in SZ compound heterozygotes, but the severity of lung disease is generally less than for ZZ homozygotes. Individuals with the MZ, MS, or SS genotypes may have slightly impaired lung or liver function. Thus, while overt AATD is considered a recessive condition, the alleles are codominant in their influence on AAT levels and associated risk of disease. There is also a strong gene–environment interaction with tobacco smoking, which can inactivate AAT, further decreasing the level of active protein and greatly increasing the risk of lung disease in susceptible genotypes.

Testing for the S and Z alleles may be performed by isoelectric focusing or DNA-based testing. Isoelectric focusing has the advantage that it will pick up other rare alleles that lead to altered protein mobility, whereas the DNA-based tests target only the two known mutations. However, both methods fail to detect rare null mutations that lead to complete loss of protein and, therefore, it is also important to measure the level of AAT in the plasma. This may be followed up with sequencing of the entire *SERPINA1* gene if rare alleles are suspected. Recommendations for genetic testing have been developed by a joint task force of the American Thoracic Society and European Respiratory Society.[45]

■ Pulmonary Arterial Hypertension

PAH (OMIM 178600) may be idiopathic (IPAH) or associated with an underlying condition, such as connective tissue disease, congenital heart defect, or HIV infection (APAH) (see Chapter 72). About 6% of IPAH patients have a family history. PAH is inherited as an autosomal dominant trait with reduced penetrance; on average, only about 27% of mutation carriers develop symptomatic disease. It is more common in females than males, and the gender-specific penetrances are estimated at 42% and 14%, respectively.[46] Initial suggestions of genetic anticipation have now been disproved.[46]

Mutations in the bone morphogenetic protein receptor type II (*BMPR2*) gene account for approximately 80% of familial PAH.[47,48] These are predominantly nonsense, frameshift, or splice-site mutations that lead to premature protein truncation or NMD.[49] Larger gene rearrangements also are frequent.[50,51] Mutations triggering NMD may cause less severe disease than missense mutations resulting in a stable dominant-negative protein, although data from different centers are conflicting in this regard.[52,53] *BMPR2* mutations are also found in 11% to 40% of IPAH patients without a family history.[54–56] The revised classification of PAH agreed at the fourth World Symposium created a new category—heritable PAH (HPAH)—that encompasses all patients with a detectable mutation, irrespective of family history.[57,58] *BMPR2* mutations have also been identified in patients with pulmonary veno-occlusive disease[50,59] and in PAH associated with anorexigen exposure,[60,61] congenital heart disease[62] but not in connective tissue disease.

Other genes within the bone morphogenetic protein pathway also can predispose to PAH. Mutations in the type I receptor ALK1 and its accessory protein endoglin (*ENG*) predominantly cause hereditary hemorrhagic telangiectasia (HHT). However, PAH has been reported in a number of families and may precede the onset of signs or symptoms of HHT.[63–66] Patients with HHT may also develop pulmonary arteriovenous malformations. Several mutations have also been identified in the *SMAD9* gene, which encodes Smad8, a downstream mediator of bone morphogenetic protein signaling,[67–70] and in *GDF2*, which encodes BMP9, one of the ligands that bind to the ALK1-BMPRII receptor complex.[70,71] Recent exome and genome sequencing efforts have led to the identification of numerous additional PAH genes.[70,72–75] One notable finding is that the mutation spectrum in children with PAH differs from adults, with enrichment for mutations in *TBX4,* a gene that plays a crucial role in lung development and is also associated with small patella syndrome.[76–78]

The low penetrance of PAH mutations suggests that additional genetic and/or environmental factors also play a role. The proliferative vascular changes share many features with cancer,[79–81] and analysis of affected lung tissues provides molecular support for this hypothesis, with evidence of somatic mutations, microsatellite instability, and aneuploidy.[82–84] miRs likely play an important role in PAH pathogenesis. The bone morphogenetic protein pathway regulates expression of a subset of miRs by promoting processing of the primary miR transcripts.[85,86] This pathway is attenuated in patients with *BMPR2* or *SMAD9* mutations,[68] whereas several other miRs also have been implicated in PAH, independent of mutation status.[87–92]

There is now considerable evidence for abnormalities in DNA damage and repair in PAH lung vascular cells, as well as the role and therapeutic potential of epigenetic modifications. These are too numerous to detail here; we refer the reader to several recent reviews.[24,93,94] Overall, despite the progress in understanding HPAH, relatively little is known about the genetic factors that may influence other forms of pulmonary hypertension, particularly non-Group 1, and the heterogeneous nature of the disease remains a challenge. Newer omics studies, such as proteomics and metabolomics, show promise as diagnostic biomarkers and for risk prediction and are likely to provide considerable new insight as these technologies mature.[95–97]

Heritable pulmonary veno-occlusive disease (PVOD) and pulmonary capillary hemangiomatosis (PCH) are rare and pathologically distinct forms of PAH, inherited in an autosomal recessive pattern. Biallelic mutations in *EIF2AK4*, a gene encoding eukaryotic translation initiation factor 2 alpha kinase 4, were identified as a cause of PVOD/PCH in families, and up to 25% of sporadic cases.[98,99] Whole genome sequencing in a large cohort of PAH patients identified biallelic *EIF2AK4* mutations in approximately 1%, indicating that genetic testing can be beneficial to refine the diagnosis in patients who have been misclassified.[100] This is especially important for PVOD/PCH, where response to standard PAH therapies is poor, and early lung transplantation should be considered.[101]

Idiopathic Pulmonary Fibrosis

The genetics of IPF (OMIM 178500, 614742, 614743) (see Chapter 54) parallels that of PAH in many respects. A small proportion of cases are familial, and the only significant difference in clinical presentation is an earlier age of onset. The pattern of inheritance is autosomal dominant with variable penetrance.

Familial pulmonary fibrosis (FPF) is genetically heterogeneous, but the genes involved do not all fall in a common pathway. About 3% of families have mutations in either surfactant protein A2 (*SFTPA2*) or surfactant protein C (*SFTPC*) genes, but a much larger proportion of families have mutations affecting telomerase.[102–104] Telomeres are like protective caps on the ends of chromosomes, important in maintaining genome stability. Their DNA sequence comprises many hundreds of copies of the repeat TTAGGG. Due to its position at the end of the chromosome, this sequence cannot be fully replicated and over time the number of repeats gets progressively shorter. Indeed, telomere shortening is believed to be one of the major molecular factors underlying aging. To counteract this, proliferative cells express telomerase, which catalyzes the addition of telomeric DNA. It is especially important in stem cells and germ cells but is turned off in most differentiated cells. Cancer cells frequently reactivate telomerase. Telomerase is a heteromeric complex composed of a protein with reverse transcriptase activity, encoded by the gene *TERT*, and a lncRNA (*TERC*) that provides the template for synthesizing new telomeric DNA.

The link between IPF and telomerase first came from the identification of genes causing dyskeratosis congenita, a rare multisystem genetic disorder. Patients with dyskeratosis congenita have shortened telomeres and a high incidence of pulmonary fibrosis, prompting analysis of telomere-related genes in FPF.[105] About 18% of families have now been identified with heterozygous mutations in *TERT* and about 1% with *TERC* mutations.[103,104] The average length of the telomeres modifies disease severity, and, since the telomeres become progressively shorter with each generation, families with these mutations demonstrate increasingly earlier onset of disease in successive generations, a phenomenon known as "genetic anticipation." Patients with very short telomeres are also at risk for developing aplastic anemia or dyskeratosis congenita.[104] Other genes within the telomere maintenance pathway that are mutated in IPF include *PARN*, *RTEL1*, and *DKC1*.[106–108]

For patients with IPF (i.e., without a family history), approximately 3% have a *TERT* mutation and less than 1% surfactant protein mutations. However, 25% have a telomere length below the 10th percentile in the general population, suggesting that shortened telomere length is a major risk factor for pulmonary fibrosis, even in the absence of an identifiable mutation.[109] Genomic studies of IPF lung tissue have already yielded considerable insight into the genetic changes contributing to lung fibrosis,[110] including distinct changes in gene expression,[111–113] DNA methylation patterns,[114–116] and miR expression,[117–120] although these have not as yet been translated in new therapeutic approaches.

Surfactant Metabolism Dysfunction

Genetic disorders of surfactant metabolism (OMIM 265120, 300770, 610913, 610921, 614370) range from severe neonatal respiratory distress and congenital pulmonary alveolar proteinosis to interstitial lung disease presenting in childhood or adulthood. It is important to note that acquired pulmonary alveolar proteinosis is a distinct autoimmune disorder (see Chapter 70). Autosomal recessive forms of surfactant metabolism dysfunction are caused by mutations in surfactant protein B gene (*SFTPB*)[121] or the transporter gene *ABCA3*.[122–124] Both lead to severe neonatal respiratory distress. Recessive forms of pulmonary alveolar proteinosis can also be caused by mutations in the granulocyte-macrophage colony-stimulating factor receptor subunits *CSF2RA*, which is X-linked recessive, or *CSF2RB*, autosomal recessive. *SFTPC* mutations are inherited as an autosomal dominant trait with variable penetrance. The phenotype may range from severe neonatal or childhood-onset interstitial lung disease to adult-onset pulmonary fibrosis.[125,126]

Alveolar Capillary Dysplasia

Alveolar capillary dysplasia (ACD; OMIM 265380) with misalignment of the pulmonary veins is a rare condition caused by heterozygous mutation or deletion of the *FOXF1* gene on chromosome 16.[127] It is usually lethal in infancy and, therefore, mutations are not inherited from an affected parent; rather, they occur de novo in the oocyte or sperm or in the very early embryo. However, one family has been described in which the mother had five affected children and was found to carry a missense mutation in *FOXF1,* despite being unaffected herself.[128] The mutation had arisen de novo on her paternally derived chromosome 16. The authors proposed that *FOXF1* is imprinted on the paternal allele, meaning that it is only expressed from the maternal allele. Thus, when the mutation first arose on the paternal allele, its effect was masked because only the normal, maternally derived allele was expressed; however, when the mother passed the mutation to her children, it was now on a maternally derived chromosome and was expressed, leading to ACD and multiple congenital anomalies. Subsequently, however, transmission of a paternally derived mutation has been documented, with a variable phenotype in his three children.[129] Furthermore, *FOXFI* was found to be expressed from both parental alleles in lung tissue, with no evidence of differential methylation, suggesting that it is *not* imprinted.[130]

Overall, the pattern of tissue-specific methylation and imprinting in this region of chromosome 16 is complex, and parent-of-origin effects in ACD may be due to differential methylation of the *FOXF1* enhancer region, rather than the gene itself.[131] Single nucleotide variants in this enhancer region also may modulate the ACD phenotype.[132] Lastly, a small number of families have been reported where multiple affected babies are born to parents who have no evidence of a mutation in their blood DNA by standard genetic testing methods. This situation may arise due to gonadal mosaicism, in which the mutation has arisen post-zygotically in the parent and is present in a proportion of germ cells. Highly sensitive mutation detection methods may pick up a low level of mutant molecules in blood DNA, helping to accurately counsel the parents as to their recurrence risk.[133]

Primary Ciliary Dyskinesia

Primary ciliary dyskinesia (PCD; numerous OMIM numbers) is predominantly an autosomal recessive disorder, with occasional X-linked recessive inheritance, in which abnormalities of the cilia lead to frequent respiratory infections and chronic lung disease (see Chapter 6). Other manifestations of the condition may include situs inversus and infertility. PCD is genetically very heterogeneous; mutations in more than 40 different genes have so far been identified.[134] Many of these genes encode critical structural components of cilia, such as axonemal dynein, or affect the assembly or motility of cilia. A significant proportion of cases still have no identifiable mutation and, thus, it is expected that more genes will be identified. This very high level of genetic heterogeneity represents a significant challenge, but the ability to sequence the entire exome of affected individuals is improving the ability to identify additional genes and is enabling genotype-phenotype correlations to be made.[135,136]

■ Sickle Cell Disease

Sickle cell disease (OMIM 603903) is the most common autosomal recessive disease in individuals of African ancestry (see Chapter 95). Although primarily a blood disorder, it can give rise to significant pulmonary complications, including acute chest syndrome, emboli, and pulmonary hypertension. It is caused by a single A>T mutation in the beta-globin gene that leads to substitution of valine in place of glutamic acid at codon 6. The resulting hemoglobin molecule has reduced solubility compared to the wild-type protein, an example of a mutation that causes gain of an abnormal function. Heterozygous carriers of the mutation have increased resistance to malaria, which is believed to account for the high frequency of the mutation in regions where malaria is or was previously endemic.

Persistence of fetal hemoglobin (HbF) beyond infancy can ameliorate the severity of sickle cell disease. This observation underlies the rationale for treatment with hydroxyurea, which boosts HbF levels, reducing pain crises, the need for blood transfusions, and the incidence of acute chest syndrome.

HbF levels are genetically determined by polymorphisms at several loci, and these SNPs also associate with the frequency of pain crises.[137] One of these genes, *BCL11A*, is a transcription factor that normally silences HbF expression. Deletion of *BCL11A* leads to persistence of fetal hemoglobin, and this gene is now the target of some exciting clinical trials testing gene therapy approaches for sickle cell disease. One study uses CRISPR-Cas9 gene editing to disrupt an erythroid-specific enhancer of *BCL11A* in patients' own hematopoietic stem cells, which are then transplanted back into the patient, with the potential for long-term engraftment and expression of HbF.[138] Initial results from the first patient, followed for more than a year, show a high level of HbF expression and a reduction in pain crises. By boosting HbF levels, rather than attempting to correct to the sickle cell mutation, this approach is also being trialed for beta-thalassemia.[138] A similar approach using posttranscriptional silencing of *BCL11A* by RNA interference also has shown promising results in early clinical trials.[139]

GENETIC BASIS OF COMMON LUNG DISEASES

Common lung diseases such as asthma and COPD are not inherited as strong Mendelian traits. However, they may show evidence of familial clustering, suggesting that there is a genetic component to their etiology. The proportion of variation that is estimated to come from genetic factors is termed the "heritability" of the trait, high heritability indicating a strong genetic component.

Since common complex diseases do not show clear segregation patterns within families, traditional model-based (parametric) mapping studies cannot be used. Instead, nonparametric methods have been employed across large collections of small family groupings, such as affected sib pairs. Early studies used a candidate gene approach. More recently genome-wide association studies (GWAS) have been used in very large case-control cohorts. Both types of study utilize some of the millions of polymorphic genetic variants throughout the genome and look for a statistically significant association between these genetic markers and the trait of interest. Single nucleotide polymorphisms (SNPs) are now the most commonly used genetic variants, as microarray technology enables simultaneous analysis of more than one million SNPs on a single array. Correlations can also be tested with clinical parameters and biomarkers such as exhaled nitric oxide, serum IgE, and FEV_1, both for genetic and epigenetic markers.[23,140]

Analyzing so many variants across thousands of samples raises the problem of multiple testing, whereby the large number of comparisons between cases and controls greatly increases the likelihood that differences will be identified just by chance. To reduce the number of false-positive results, stringent correction for multiple testing is required. Also, cases and controls must be carefully matched to ensure there is no hidden population stratification that might distort allele frequencies.

It is important to note that many of these SNPs are in noncoding regions of the genome and do not directly affect gene regulation or protein function. Rather, they are markers that tag a nearby sequence that may modulate disease risk. In comparison to Mendelian diseases, where mutations confer a high risk of developing the condition, the relative risks for loci identified in GWAS are generally quite small. They have little or no predictive value and so in this respect their clinical utility is limited; the value of these studies is in identifying new pathways and targets for therapeutic intervention.[141] Significant resources have been invested in GWAS in a wide range of diseases, and the challenge is to identify the functional variants and fully realize the translational potential of this research. A new and powerful approach is systems biology, which aims to integrate multiple types of "omics" data, such as GWAS, genome-wide expression data, miRs, and epigenomics into networks that identify new pathways and biologic connections. Furthermore, the advent of polygenic risk scores—which combine the effects of individual SNPs into an aggregate odds ratio—will likely improve the clinical utility of GWAS results in the future.

The literature on GWAS in common lung diseases is large and continues to expand rapidly. In this brief space, it is not possible to discuss these studies in any detail, especially given the complexities of racial and ethnic differences in SNP frequencies and the many subphenotypes that have been studied. Therefore, only a brief overview of some of the major candidate loci will be provided; the reader is referred to reviews that can be used as a starting point for in-depth reading.

■ Asthma

Asthma (see Chapters 43–45) has a high heritability and, therefore, has been a good candidate for GWAS. Some of the strongest loci identified thus far include HLA-DQ, Orosomucoid-like 3 (*ORMDL3*), and several interleukins and interleukin receptors.[142,143] *ORMDL3* is inducible in the bronchial epithelium and, in mice, it has been shown to regulate metalloproteinases and several cytokines.[144] Residing in the endoplasmic reticulum (ER), *ORMDL3* has also been linked to ER stress, as well as to playing a critical role in sphingolipid biosynthesis.[145,146] SNPs in the same region also modulate expression of a neighboring gene, gasdermin-B (*GSDMB*), part of a family of genes implicated in regulating epithelial cell apoptosis. The *ORMDL3/GSDMB* locus, originally identified in cohorts of European origin, was also validated as a critical asthma susceptibility locus in African-American children.[147,148]

African genomes can help to refine candidate genetic regions, since regions of linkage disequilibrium—where SNPs travel together through the generations without being separated by recombination—are smaller than in European genomes. In the case of *GSDMB*, this approach pinpointed a single causative SNP that directly affects splicing of *GSDMB*.[148,149] Several genes are also associated with response to bronchodilators.[150]

Hispanic and African American populations have a higher incidence of severe asthma but are understudied in comparison to Caucasians and represent an important research priority. As described above, trans-ethnic studies can be very helpful in refining the localization of candidate loci that are in common between different races. However, distinct loci also exist, both in disease susceptibility and response to therapy, underlining the importance of inclusive research to address health disparities.[151–153] Ultimately, translating GWAS hits to functional biology is one of the biggest challenges of studying the role of genetic variants in common diseases; however, high throughput functional screening assays are increasingly effective as way of validating findings from GWAS and whole genome sequencing studies.[154]

Environmental factors, such as air pollution and smoking, are known to be important modulators of asthma risk.[29] This may be mediated, at least in part, through epigenetic changes affecting DNA methylation, histone acetylation, and miR expression.[22] Changes in DNA methylation directly regulate the arginase–nitric oxide pathway,[26,155] and distinct methylation profiles have been identified in asthmatic children compared to controls.[156] Expression studies of the effect of PM2.5 on nasal airway epithelial cultures identified significant transcriptomic changes, including drivers of mucus metaplasia and mucociliary clearance that may contribute to respiratory disorders such as asthma and COPD.[157]

■ Chronic Obstructive Pulmonary Disease

As described previously, the strongest genetic risk factor for COPD (see Chapters 37 and 38) is a mutation in the *SERPINA1* gene that encodes AAT, a risk that is further heightened by tobacco smoke exposure. More common variants with smaller effect size include the nicotine receptors *CHRNA3* and *CHRNA5*, hedgehog-interacting protein (*HHIP*), and *FAM13A*.[158] Smoking is a major risk factor for COPD and as mentioned previously, induces many epigenetic changes in the lung. Altered DNA methylation patterns have been identified in COPD patients in comparison with controls[159] and may be related to response to therapy,[160] while histone deacetylase activity is decreased.[161] Importantly, methylation changes associated with cigarette smoking are reversible with time after quitting,[30] and epigenetic changes offer promising targets for drug therapy.[31]

■ Sarcoidosis

Relatively little is known about genetic susceptibility to sarcoidosis (see Chapter 53), and despite its prevalence in African Americans, early studies were mainly conducted in cohorts of European ancestry.[162,163] Surprisingly, emerging data suggest common risk loci across multiple different ethnic groups,[164–166] a marked contrast from the heterogeneity in GWAS data for some other diseases. Key loci identified from these studies include the *ANXA11* gene and several HLA subtypes, with complement C4A or C4B deficiency also suggested.[167]

TARGETED THERAPIES FOR GENETIC DISEASE

The completion of the human genome project led to high expectations (and in some cases, hype) of a new era of personalized medicine. The first arena in which this has been realized is in the treatment of cancer. Drugs such as imatinib (for chronic myeloid leukemia) and trastuzumab (in breast cancer) target specific gene rearrangements or amplifications that occur within the tumor. Several drugs are approved to target epidermal growth factor receptor (EGFR) in non–small-cell lung cancer. Targeted lung cancer therapies are discussed in detail in chapter 114. Progress in other fields has been slower, but some recent advances show great promise, especially for CF.

Initial hopes for gene replacement therapy in CF failed to live up to expectations, but detailed characterization of the types of mutations and their functional consequences are now translating into new therapies. One approach is to promote read-through of nonsense mutations with a small molecule called ataluren (PTC124).[168] This reduces the recognition of a premature stop codon and allows the ribosome to translate a full-length protein. The same approach has been tried previously with aminoglycoside antibiotics, but ataluren is more potent and has fewer adverse effects.[169] In theory it should work for any nonsense mutation, but in practice some mutant transcripts are rapidly degraded by nonsense-mediated decay. Logically, therefore, the approach has proved to be most effective for mutations that are relatively stable and not subject to NMD.[170] After positive results in mouse models of CF and Duchenne muscular dystrophy, ataluren was given orphan drug designation by the U.S. Food and Drug Administration (FDA) and showed promising results in phase 2 CF clinical trials.[171] However, subsequent studies have failed to show a statistically significant difference in lung function or pulmonary exacerbations.[172,173] The drug is approved in Europe for the treatment of Duchenne muscular dystrophy and has shown promising in vitro results against nonsense mutations in PAH vascular cells.[174]

In cases where a full-length CFTR protein is made, but either mislocalizes (class II) or is an inefficient chloride transporter (classes III and IV), drugs are being tested that could improve trafficking to the membrane and improve transporter function. Ivacaftor (VX-770) was found to be effective in rescuing channel gating function of the G551D mutation,[175] a class III mutation with a frequency of 3% to 5%. A randomized placebo-controlled trial of ivacaftor produced exciting results, with highly significant improvements in FEV_1, sweat chloride levels, weight, and quality of life scores.[176] However, therapies to help the majority of patients with CF who are homozygous for F508del were still needed.

The next agent developed was tezacaftor (VX-661), which rescues the mislocalization of F508del and restores it to the cell membrane. Tezacaftor is known as a CFTR corrector, whereas ivacaftor is a potentiator of channel function. The two drugs in combination were shown to be effective in patients with F508del/F508del and F508del/G551D genotypes.[177] However, in some patients, either the second mutation leads to lack of protein production, or the mutant protein fails to respond to tezacaftor/ivacaftor. These are dubbed “minimal function” mutations.

The latest addition to this remarkable therapeutic family is elexacaftor (VX-445), also a CFTR corrector. In combination with tezacaftor and ivacaftor, elexacaftor significantly improved lung function and reduced pulmonary exacerbations in patients with one copy of F508del and a minimal function mutation.[178] This triple combination therapy—known as Trikafta—has since been approved by the FDA for the treatment of CF patients with at least one copy of F508del. This covers at least 90% of patients in most populations. While this is an incredible success story, a small proportion of patients remain who do not benefit from the current combinations of drugs.

These therapies also do not address some of the extrapulmonary manifestations of CF, such as meconium ileus in newborns, and may not reverse existing lung damage. Nevertheless, the message is that careful study of the effects of specific genetic mutations can ultimately translate into novel therapies that directly target the underlying molecular defect.

Other lung diseases are lagging compared with CF, although many do not have the benefit of more than two decades of research on a single gene. However, new therapeutic targets are starting to emerge from some of the research summarized earlier, particularly at the epigenetic level. Several approaches to improving BMPR2 signaling in HPAH are being studied.[174,179–183] In particular, Sotatercept, a soluble TGF-beta/BMP ligand trap, has shown promising results in early clinical trials.[184] At the epigenetic level, histone deacetylase inhibitors and bromodomain and extraterminal domain (BET) inhibitors have been proposed as a possible therapy in PAH,[24,185] whereas corticosteroid-resistant COPD may benefit from increasing HDAC2 activity.[31] Meanwhile, as discussed previously, the potential for therapeutic uses of gene editing is being realized in sickle cell disease. As our understanding of the effect of specific genetic mutations and epigenetic modifications continues to deepen, the future for targeted therapeutic intervention is bright.

CHAPTER 8

Stem Cells and Respiratory Disease: Prospects for the Future

Konstantinos-Dionysios Alysandratos*
Michael J. Herriges*
Darrell N. Kotton*

INTRODUCTION

Advances in stem cell research offer unprecedented opportunities to develop new treatments, disease models, and drug screens for previously untreatable conditions. These discoveries have captivated the imagination of the lay press and have inspired hope in patients, clinicians, and scientists. Inevitably, in an emerging new field, there are false starts that accompany promising discoveries. If rigorous researchers in the field have difficulty discerning hype from hope, what is a busy clinician to do when confronted with basic questions, such as: "Is stem cell therapy available for my lung disease?" or "Shall I bank my baby's cord blood in case he/she develops cystic fibrosis or emphysema?" This chapter is designed to describe the quickening pace of stem cell and regenerative medicine research related to lung disease and to place the latest discoveries in a historic context, before discussing future prospects.

Stem cells have been found in an increasing number of tissues whose biology is characterized by rapid turnover of differentiated cells. In these tissues, for example, blood, skin, and intestine, a stem cell hierarchy has been described where rare stem cells proliferate occasionally, giving rise to stem cell daughters or to progenitors that can proliferate rapidly and differentiate into mature cells required for the function of that tissue. These properties of self-renewal and differentiation are the classic hallmarks of stem cells, and their importance in homeostatic maintenance of the blood, skin, and intestine are well accepted.[1–3] These features also make stem cells attractive vehicles for clinical applications such as the reconstitution of injured or diseased tissues. Several decades of research, including the seminal bone marrow transplantation work of Till and McCullough,[4] has rigorously proved that the hematopoietic stem cell, a cell that constitutes 1 in 10,000 bone marrow cells, can be delivered to a recipient by simple intravenous infusion, reconstituting all cells of the bone marrow and circulating blood for the lifetime of the recipient.[1]

Given the virtually unlimited self-renewing capacity and blood differentiation repertoire of hematopoietic stem cells, most pulmonologists are surprised to learn that cells of similar capacity have not been reproducibly proven to exist in the lung and may not be necessary for the homeostasis of an organ with a quiescent epithelium that contrasts with the rapidly self-renewing epithelia of intestine and skin.

LUNG EPITHELIAL RESPONSES TO INJURY

Because the unperturbed adult lung epithelium displays remarkably slow cell turnover, the post-injury or disease responses of human or animal lung have been studied to elucidate both the proliferation potential and differentiation repertoire of various lung cell types. These injury models have been used to search for potential specialized lung cells that might exhibit stem cell properties, such as self-renewal and multipotent differentiation (reviewed by Rawlins and Hogan).[5] In the lung many types of functionally mature cells appear to be endowed with the ability to proliferate, if needed, and to subsequently differentiate, with the responding cell type depending on the type and severity of injury. In this way, the biology of the lung epithelium may be more akin to that of other quiescent endoderm-derived tissues, such as the liver and pancreas, whose tissues have less turnover and may be repaired by proliferating mature cells or facultative progenitors, depending on the type of injury.[6] Beginning in the 1970s, morphologic studies of human and animal lungs defined subsets of lung epithelia with proliferative capacity, revealing basal and secretory (club) cells (previously called Clara cells) of the proximal airway, and alveolar epithelial type 2 cells of the distal lung parenchyma all had the capacity to enter cell cycle in response to lung injury.[7–15] More recently, thymidine-labeling techniques have been replaced by newer methods of identifying proliferating cells or tracking their progeny. These studies have emphasized that most lung epithelial cells, except for airway ciliated cells or alveolar epithelial type 1 cells, can proliferate after injury in a remarkably resilient organ where many differentiated epithelial subtypes contribute to tissue repair.[5,16–20]

Beyond assessing the proliferation of cells in the adult lung, the classic developmental biologist's method of "lineage tagging" cells has allowed investigators to follow the origin of lung epithelial cells during development, and to assess where they go upon aging or after injury.[16,21–23] It is now well established that the many types of epithelial cells in the adult lung arise during development from a few progenitor cells in the embryonic foregut endoderm.[24] The concept has become generally accepted that a limited number of lung epithelial cell types are specified during embryonic development and sustain their committed differentiated state throughout life.[23] In the nascent field of stem cell research, most investigators agree that multipotent, bona fide lung epithelial progenitors exist, if only fleetingly early in embryonic development.[24,25] It remains unclear, however, whether any specialized progenitors or stem cells similar to these embryonic endodermal precursors remain in the lung postnatally or are rederived after injury.

EVOLVING STUDIES IN THE SEARCH FOR LUNG STEM CELLS

With so many proliferation-competent epithelial cells in the adult lung able to participate in post-injury repair, some investigators have begun to wonder which of these cells are responsible for functional epithelial repair. The search for specialized reparative lung cells in recent years has been propelled by the emergence of specific and sensitive molecular biology tools and laboratory instruments that can refine our previous understanding of lung biology (Fig. 8-1). New studies suggest that a much greater diversity exists within the previously identified broad classifications of lung airway and alveolar epithelial cells.[26] For example, the response of mouse lung to recover from naphthalene exposure, an injury that depletes the lung of most secretory cells (identified by the marker secretoglobin family 1A member 1 [SCGB1A1], also known as club cell secretory protein [CCSP or CC10]), revealed a small subset of airway progenitors, called "variant club cells" (v-club cells; previously variant Clara cells).[27–29] These cells expressed *Scgb1a1*, but they lacked expression of the cytochrome P450 2F2 isoenzyme (encoded by *Cyp2f2*) that is responsible for generation of the toxic naphthalene metabolites that kill other secretory cells, rendering them resistant to naphthalene injury. Figure 8-1 Epithelial cell types of the murine lung and their progenitor capacity. **A.** The murine lung contains a diverse population of epithelial lineages that are each restricted to specific compartments of the respiratory system. **B.** While the lung is largely quiescent during homeostasis, many of these lineages may serve as facultative progenitors capable of self-renewal and differentiation following injury or transplantation. AEC1, alveolar epithelial type 1 cell; AEC2, alveolar epithelial type 2 cell; BASC, bronchioalveolar stem cell; LNEP, lineage negative epithelial progenitor. *(Reproduced with permission from Alysandratos KD, Herriges MJ, Kotton DN. Epithelial stem and progenitor cells in lung repair and regeneration. Annu Rev Physiol. 2021;83:529–550.)*

cells survived and rapidly reconstituted both secretory and ciliated populations of the injured airway. Most intriguing was the observation that this rare subset of *Scgb1a1+* cells appeared to reside in two specialized microanatomic locations or niches: adjacent to neuroepithelial bodies of the airways and at bronchioalveolar duct junctions. This observation remains one of the most convincing examples to date, suggesting the lung contains progenitor niches, or microanatomic cell compartments with specialized stem or progenitor cells.

A remarkable study by Kim et al. proposed that some rare *Scgb1a1+* progenitors located at the bronchioalveolar duct junction in mice may possess the capacity to reconstitute both airway and alveolar epithelia, suggesting the rodent lung contains rare, multipotent, "bronchioalveolar stem cells" (BASCs).[30] Until recently, the existence of BASCs was contested in experimental work by Hogan et al.[21] using *Scgb1a1*-lineage tracing, which should label the putative BASC population. These investigators found that during development and injury repair these cells gave rise only to conducting airway but not alveolar epithelia. In contrast, after bleomycin induced lung injury in later publications, *Scgb1a1+* lineage traced cells were capable of generating alveolar epithelial cells, although their contribution was limited and they did not appear to expand significantly.[22,31] Two recent studies using novel lineage tracing approaches provided more convincing evidence that BASCs are indeed a rare but distinct population of cells residing at the mouse bronchioalveolar duct junction and are capable of giving rise to both airway and alveolar epithelia to some degree following injury.[32–34] The relevance of these emerging murine BASC studies to human lung biology remains uncertain given that the anatomy of the most distal airways differs between the two species, and the anatomic equivalent of the murine bronchioalveolar duct junction is not present in the human terminal airways, which end as sequentially tapering terminal bronchioles, respiratory bronchioles, and alveolar ducts.[35,36]

In the more proximal airways, such as the mouse trachea or human bronchi, investigators have also found remarkable subsets of basal cells that contain extensive proliferative potential and a multipotent differentiation repertoire consisting of the capacity to give rise to basal cells, secretory cells, ciliated cells, neuroendocrine cells, ionocytes, and tuft cells.[37–43] With the advent of modern flow cytometry, these cells can now be sorted to purity, allowing the cataloging of protein markers (such as Trp63, NGFR, KRT5, or KRT14) that identify these cells as well as the delineation of their global transcriptome by microarray analysis or single-cell RNA sequencing.[37,42–44] The capacity to purify, expand in culture, and differentiate basal cells has resulted in a number of publications in recent years with important implications for those searching for lung stem or progenitor cells.[37,42–45] First, these studies have confirmed that heterogeneity within the previously limited subsets of lung epithelial cells is indeed much greater than was appreciated a decade ago.[26,46] Second, the studies have revealed the impressive proliferative potential and differentiation repertoire of some subtypes of single lung epithelial cells (such as basal cells), which can expand almost indefinitely in vitro, similar to classically studied stem cells of the skin.[37–45]

The surface epithelium of the conducting airways of humans and other mammals and of the proximal trachea of mice, forms crypts where the submucosal glands reside.[47–49] These glands are composed of luminal epithelial cells as well as basally located myoepithelial cells and have long been identified as airway niches that harbor proliferative cells able to give rise to surface airway epithelial cells following severe airway injury, providing additional epithelial progenitors able to participate in airway repair.[50–53]

Taken together, this body of work supports the concept that basal cells can function as tissue-specific stem cells of the conducting airway epithelium, secretory lineages can serve as facultative progenitors after certain injuries, and, following severe injury of the surface airway epithelium, the submucosal gland epithelial cells also can serve as a facultative progenitor cell population.

While there is a quickly growing list of stem/progenitor candidate cells able to reconstitute the conducting airway epithelium, the alveolar epithelial type 2 cell to date remains the best accepted progenitor of the lung alveolus;[54] however, the question of whether all alveolar type 2 cells or an "elite" minority are capable of functioning as progenitor cells remains unresolved.[55–57] Adding further complexity to this question, a growing number of recent reports suggest that, depending on the extent and type of injury to the alveolar epithelium, several alternative subsets of distal airway epithelial cells might serve as facultative progenitors that can also contribute to regeneration of the alveolar epithelium following injury. The first of these reports suggested that cells expressing airway basal cell markers in mice (TRP63+/KRT5+/KRT14+) following severe influenza injury undergo rapid proliferation and expand in regions of the distal lung as discrete KRT5+ clusters of cells, termed "pods".[45] Although the authors concluded that KRT5+ pods subsequently express alveolar markers such as the alveolar type 1 cell marker PDPN, the contribution of KRT5+ pods directly to the alveolar epithelium remains in doubt because (1) lineage tracing of *Krt14+* cells was induced following the initiation of injury, thus limiting the interpretation of the in vivo differentiation repertoire of these cells; (2) subsequent reports have not validated differentiation of *Trp63+/Krt5+* cells into alveolar cells;[58–60] and (3) PDPN is not an alveolar type 1 cell-specific marker, as it is also expressed in TRP63+ airway basal cells, limiting its use as an alveolar marker. Separate work by Chapman and colleagues has suggested that an alternative subpopulation of mouse epithelium, presumably in the airway, expressing the integrins alpha6 and beta4 ($\alpha6\beta4$), but little or no SFTPC, is capable of proliferating in response to lung injury, and after purification from mouse lungs displayed remarkable potential for multipotent airway and alveolar differentiation.[61] A subsequent study from this group showed that cells residing in the mouse distal airways, termed *lineage negative epithelial progenitors (LNEPs)*, proliferated following influenza injury and were a major cell type contributing to the previously described KRT5+ pods.[62] Orthotopic transplantation of LNEPs into influenza-injured mice demonstrated their multipotent differentiation to both airway and alveolar cell fates.[62] A follow-up study determined that LNEPs are composed of both *Trp63+* and *Trp63-* cells and that local hypoxia through hypoxia-inducible factor 1a (HIF1a) is responsible for the Notch signaling mediated expansion of KRT5+ basal-like cells. A recent study by the same group determined that an H2-K1^{high} subset of *Scgb1a1*-traced cells, quiescent in normal murine lungs, was capable of expanding in vivo after bleomycin-induced lung injury and gave rise to alveolar and airway lineages in vitro. Transplantation of FACS purified H2-K1^{high} cells into bleomycin-injured mice resulted in differentiation into alveolar lineages and improved oxygenation in the recipients.[60] These H2-K1^{high} cells appeared to be distinct from BASCs based on their absence of *Sftpc* expression and were distinct from the previously described *Trp63+* LNEPs. H2-K1^{high} cells expanded only following bleomycin and not influenza injury, suggesting that the type of progenitor cells that mobilize to regenerate the alveolar epithelium depends on the nature of the injury. In summary, an extensive literature dating back to the 1970s has established alveolar epithelial type 2 cells as the predominant facultative progenitors of the distal lung in both mice and humans,[63–65] but an emerging recent literature, based almost entirely on mouse studies, suggests there may be alternative rare progenitors with alveolar epithelial competence that can be harnessed after specific injuries (reviewed in Alysandratos et al.).[20]

PRELIMINARY ATTEMPTS TO HARNESS LUNG PROGENITORS FOR ENGRAFTMENT OR BIOENGINEERED LUNG TISSUE

While the therapeutic application of these progenitor populations remains years away, it is already clear that the lessons learned from studying the biology of progenitor cells in both mouse models and humans with lung disease can be applied to clinical settings. For example, many publications now demonstrate that communications between some of the best-studied lung epithelial progenitors and their neighbors, either in the epithelium or surrounding lung mesenchyme, helps to regulate the fine balance between progenitor self-renewal and differentiation.[18,46,66–71] Perturbations in these communications, controlled by familiar developmental signaling molecules (such as Wnt, Notch, FGF, retinoic acid, and TGFβ) disturb the balance of lung epithelial homeostasis[72] and contribute to the disordered histopathology and physiology of many lung diseases, including cystic fibrosis, emphysema, idiopathic pulmonary fibrosis, and asthma.[46,73,74] The increased understanding provided by studying the basic biology of lung progenitors and epithelial–mesenchymal interactions has thus allowed a more complete understanding of clinical disease[73,75] and already is being applied for the development of new pharmaceuticals designed to modulate the above signaling pathways. The long-term goal of achieving sophisticated drug therapies for a variety of lung diseases is likely to ultimately involve activation of endogenous lung progenitors or mature epithelia to accomplish reparative reepithelialization to avoid pathologic lung remodeling.[83]

Common to most of the aforementioned studies evaluating the differentiation repertoire of purified lung progenitor candidates is the suggestion that if an effective technique for grafting these cells into injured lungs were available, these progenitors might be used to regenerate injured epithelia in patients. In recent years, a number of studies have reported data supporting the capacity of transplanted epithelial progenitor[60,62,76–81] or mature cells[82] to survive in injured mouse lungs and express lung epithelial markers. Despite use of the term *engraftment* in several of the above studies, it remains unclear whether these cells are truly "engrafted" as this will require proof that the donor cells are long-lived as well as structurally and functionally integrated into recipient lungs. Importantly, physiologic improvement of injured mouse lungs after cell transplantation, as described in some of the above reports, might be explained by paracrine effects or transient secondary reparative effects on recipient lung tissue rather than by direct, durable replacement of the epithelium with functional cells. Furthermore, due to the lack of competitive repopulation assays it remains unclear which of the several candidate populations would have the highest potential to reconstitute the injured epithelium following transplantation. The contribution of the exogenously delivered cells relative to surviving intrinsic progenitors also is unknown. Furthermore, translation of these experimental mouse therapies to humans will be required if this approach is to be clinically applied in the future.

The prospect of engineering entirely new bioartificial lungs from these cells has also been proposed to meet the needs of growing numbers of patients with end-stage lung diseases who require lung transplantation. Pioneering studies in tissue engineering[84,85] have attempted to develop methods for preparing lung scaffolds or bioartificial lungs that might surmount this highest hurdle in our field: a method for delivering candidate progenitors or lung reparative cells in vivo for engineered lung regeneration. For example, the laboratories of Harald Ott and Laura Niklasson in 2010 both published a technique of engineering bioartificial lungs through the method of detergent-based decellularization of rodent lungs. This method leaves the 3D architecture of the lung matrix intact while stripping away rodent cells. This matrix then served as a scaffold upon which rodent or human cells were adhered to generate "recellularized" lung tissue able to carry out gas exchange in vitro or even in vivo after transplantation.[84,85] More recently, Dorrello et al. developed a rat model of epithelial-only decellularization, which maintains the vasculature and basement membrane integrity. The resulting grafts were recellularized with human adult pulmonary cells and pluripotent stem cell–derived alveolar progenitors.[86] Although the complexity of human lung has made the generation of a functional bioengineered whole lung a daunting task, the combination of targeted decellularization and recellularization of the lung epithelium and ex vivo lung perfusion are promising early steps toward achieving the goal of increasing the availability of acceptable donor lungs.[87]

CONTROVERSIAL CLAIMS OF PARADIGM-SHIFTING STEM CELL RESEARCH DISCOVERIES

These aforementioned studies of lung epithelial injury, proliferation, and regeneration are slowly defining and refining our understanding of candidate lung epithelial progenitors, but there are occasional studies that challenge earlier paradigms of lung development and repair after injury. In the 1990s and early 2000s, for example, a wave of publications claimed that cells within the bone marrow, such as mesenchymal stromal cells (also known as mesenchymal stem cells [MSCs]) or hematopoietic stem cells, could circulate to the lung and give rise to almost any type of differentiated lung epithelial or vascular endothelial cell. Similar findings were reported when examining injured hearts, brains, livers, and other organs, creating understandable excitement (reviewed by Weiss et al. and Wagers and Weissman[46,89]). Clinical trials were rapidly planned to expose patients to injections of bone marrow–derived cells in the hope of reconstituting degenerative or injured tissues. The opportunity for financial profit inspired companies to promote the banking of cord blood from babies, with glossy pamphlets suggesting to expectant parents that umbilical cord blood containing "stem cells" (now more appropriately called HSCs and MSCs) had the potential to treat diabetes, cystic fibrosis, Parkinson's disease, strokes, or a myriad of other diseases. These diseases might be treated with banked cord blood if, indeed, circulating blood or bone marrow–derived cells could form reconstituting cells for each relevant organ. In hindsight, the launch of some clinical trials and the promotion of cord blood as a panacea was premature as it was based on a first wave of controversial published literature. Advances in laboratory instruments and follow-up laboratory studies begun in 2000 slowly revealed that artifacts, such as autofluorescence, nonspecific antibody labeling, and the fusion of marrow-derived myeloid cells with recipient tissues were actually responsible for the bulk of initial observations and misinterpretations of bone marrow–stem cell engraftment.[88,89] Yet today, several for-profit clinics continue to promote their unproven, direct-to-consumer "stem cell" interventions based on the now-debunked stem cell plasticity literature from the 1990s to early 2000s.[88,90] Such businesses have been taking advantage of the confusion regarding the identity and properties of MSCs from various sources[91] and administer autologous, often crude cell preparations such as the adipose tissue–derived stromal vascular fraction, for a variety of indications, including respiratory diseases.[92] Culture-expanded MSCs after transplantation may induce potentially important indirect, paracrine, or immunomodulatory effects on injured lung tissues that need to be demonstrated in well-designed and powered clinical trials. Nevertheless, in the view of these authors, existing evidence does not support their use in approaches designed to directly regenerate the lung epithelium.[93–95]

ONE CELL TO RULE THEM ALL: PLURIPOTENT STEM CELLS

Because it remains controversial whether an endogenous or transplanted lung cell possesses broad multipotency or the capacity to produce every type of lung cell, some investigators have chosen to focus their research on the de novo derivation of lung lineages in vitro from pluripotent stem cells (PSCs), such as embryonic stem cells (ESCs), which have well-established potential to generate all cell types in the body,[96] including all lung cells (at least after injection into mouse embryos). The controversy over human ESC research, unlike other stem cell fields, has not been focused on the differentiation potential of the cells, but rather on the ethical debate over whether it is permissible to utilize for research cells that are derived from a preimplantation human blastocyst embryo (typically those unused from fertility clinics) and whether PSCs that are biologically similar to ESCs might be derived from postnatal patients. Solutions to these controversies and questions were provided in the remarkable discovery of reprogramming technology by Dr. Shinya Yamanaka in 2006. Yamanaka's work revealed that four transcription factors (Oct4, Klf4, Sox2, and cMyc) transferred into cells could reset the epigenetic state of somatic cells, such as skin fibroblasts, into an embryonic-like state virtually indistinguishable from ES cells.[103] Reproduction and refinement of this discovery established reprogramming as an accepted technique to engineer induced pluripotent stem cells (iPSCs) from dermal fibroblasts or from peripheral blood cells, such as those obtained from simple skin punch biopsies, or banked blood (reviewed by Stadtfeld and Hochedlinger[104]). Like ESCs, the broad differentiation repertoire of iPSCs suggests their potential to form any desired somatic cell type, including lung epithelium.[97] In contrast to ESCs, iPSCs are genetically identical to the individual from whom they are derived, raising the prospect of utilizing iPSCs for autologous cell-based therapies without risk of rejection. Yamanaka, together with his predecessor, Sir Jon Gurdon, who discovered reprogramming approaches in tadpoles 50 years earlier, were awarded the 2012 Nobel Prize in Physiology or Medicine for their paradigm-shifting discoveries.[105]

The key advance that enabled the derivation of lung progenitors from PSCs (ESCs and iPSCs) came with the discovery by Keller et al. that the soluble growth factor activin A (hereafter activin) induced the differentiation of these PSCs into the germ layer, definitive endoderm.[100] Since the lung develops from this germ layer, emerging from the anterior foregut endoderm by budding and then branching, the derivation of definitive endoderm from ESCs was a key milestone on the way to generating lung epithelial cells from PSCs.[102] Keller's discovery was based on a careful study of how the embryo develops in vivo. Secreted nodal protein from the node of the embryo is known to differentiate embryonic cells of the epiblast into primitive streak and then into definitive endodermal progenitors within the anterior region of this primitive streak. Since activin binds similar receptors to nodal protein, Keller et al. found that ESC cultures exposed to activin differentiated efficiently into definitive endoderm. It was not until the cellular and molecular pathways responsible for definitive endoderm induction[100] and its subsequent patterning to anterior foregut endoderm[97] were discovered that efficient generation of lung epithelial lineages was made possible.[97–99,106,107] Using expression of the *Nkx2-1* (also known as thyroid transcription factor-1 [TTF1 or

Titf1]) locus as a marker of lung lineage specification from foregut endodermal progenitors, a number of studies identified that the temporal activation of Wnt, BMP, and RA signaling is essential for lung lineage specification in vivo and can be harnessed to generate lung epithelium in vitro from PSCs.[107–111] Again, these discoveries of how to differentiate stem cells into lung progenitors through activating a sequence of developmental milestones was made possible by mimicking the published inductive signals known to be active during in vivo embryonic endoderm and lung development.[101,102] Additional studies have developed methods for further differentiating human PSC-derived NKX2-1+ progenitors into the developing cells of the proximal airways or distal alveoli, including their progeny of varying functionally mature stages. For example, 3D culture systems have now been developed for the efficient generation of functional alveolar epithelial type 2 cells that are transcriptomically and ultrastructurally similar to primary alveolar type 2 cells and capable of producing surfactant proteins and phospholipids.[112–114] In addition, airway progenitors have been generated from primordial NKX2-1+ lung progenitors and can be propagated in 3D spheres producing secretory and ciliated cells,[115,116] or most recently airway basal-like cells.[117] These studies have also highlighted the importance of better understanding the temporal relationship of developmental signaling pathways involved in lung lineage specification, differentiation, and maturation.

To establish clinically relevant pluripotent stem cell platforms for lung disease research, some investigators have developed new reprogramming technologies able to derive “clinical grade” iPSCs from human skin or blood[104] and have successfully applied these technologies to generate banks of “lung disease–specific” iPSC lines from patients with a variety of end-stage lung diseases.[118] There are an increasing number of publications demonstrating how these cells are being applied to model lung disease. For example, iPSCs generated from patients with cystic fibrosis have been differentiated into endodermal or more mature airway epithelial cells expressing the *CFTR* gene responsible for cystic fibrosis, thus modeling *CFTR* dysfunction using cells of each patient’s own genetic background and studying the effects of a pharmaceutical product designed to correct *CFTR* chloride ion flux.[117,119–121] In addition, an emerging literature has also utilized iPSCs to produce in vitro distal lung disease models by generating alveolar type 2–like cells that reveal pathogenetic mechanisms associated with children’s interstitial lung disease (chILD) due to surfactant mutations[112,122] or pulmonary fibrosis associated with Hermansky-Pudlak syndrome.[123,124] Many other groups are now focused on utilizing patient-specific iPSC lines (and ESCs) to model additional lung diseases in vitro, to screen drugs and gene therapy approaches, and to derive de novo replacement lung epithelia and endothelial cells that may one day be transplanted back into the patients from whom they have been derived (Fig. 8-2). The lessons learned from the failed attempts to deliver bone marrow–derived cells to the injured lung epithelium have taught us that delivery of iPSC-derived lung cells (or any other lung cell) in vivo will not be easy or straightforward. Still, precedent has already been set in initial clinical trials involving the transplantation of ESC- or iPSC-derived retinal pigmented epithelial cells to treat macular degeneration or dopaminergic neurons to treat Parkinson’s disease.[125,126] Animal models of Parkinson’s disease and mouse models of sickle cell disease paved the way for these new clinical trials after iPSC-derived replacement neurons or hematopoietic stem cells, respectively, resulted in clinical improvement when technology for effective differentiation and transplantation of these cells was carefully developed (reviewed in Stadtfeld and Hochedlinger[104]).

Figure 8-2 Schematic indicating approach for generating patient-specific or disease-specific induced pluripotent stem cells (iPSCs) from humans with lung disease. Peripheral blood cells or skin fibroblast cells harvested from a patient with lung disease, are reprogrammed into iPSCs using defined transcription factors. The resulting iPSCs undergo in vitro “directed differentiation” into lung epithelial or other lung lineages. These lineages can be employed for in vitro studies of disease pathogenesis modeling or high-throughput screening of drugs to predict efficacy. The cells may also undergo correction of any disease-causing gene mutations (such as ΔF508 CFTR) using various genome editing technologies. Correction may be performed in the undifferentiated state or (as shown) following directed differentiation into lung lineages. For future studies, corrected cells may be employed to tissue engineering bioartificial lungs or to develop cell-based therapy by transplantation back into the patient from whom they have been derived. Alternatively, drugs passing in vitro screening can be administered to the patient as personalized medicine.

be the most effective and most efficient way to derive desired differentiated lineages in vitro.[96] Unfortunately, little is known about many stages of embryonic lung development, a deficit that limits progress in deriving de novo mature lung epithelia from pluripotent stem cells (be they ESCs or iPSCs) in vitro and hampers our ability to properly understand and modulate repair after lung injury.

FUTURE PROSPECTS FOCUSED ON THE CLINICAL APPLICATIONS OF STEM CELLS

Given that safe clinical applications of most of the aforementioned exciting stem cell advances remain years away, how is a pulmonologist able to answer questions and respond to the pleas of patients desperate for stem cell therapies? One resource designed to help both physicians and patients access reliable information is the International Society for Stem Cell Research (ISSCR) webpage, which features a downloadable free "Patient Handbook" designed to educate the public about the promise and perils of stem cell research (*www.closerlookatstemcells.org*). The American Thoracic Society webpage equivalent also helps to objectively caution patients that most stem cell trials charging fees for claimed "treatments" have not been reviewed or substantiated by experts (*https://www.thoracic.org/patients/patient-resources/resources/stem-cell-therapy.pdf*).

At the time of publication of this chapter, a number of clinical trials are listed at clinicaltrials.gov for evaluating various cell-based therapies for several lung diseases (reviewed by Weiss et al.[46] and Ikonomou et al.[95]). Infusions of MSCs to treat patients suffering from COPD, bronchopulmonary dysplasia, bronchiolitis obliterans, asthma, idiopathic pulmonary fibrosis (IPF), pulmonary hypertension, acute respiratory distress syndrome (ARDS), or more recently acute lung injury from coronavirus infection are planned, underway, or completed.[95] Additional clinical investigations, not listed on this website, have also targeted IPF with cell-based therapy.

It is still too early to determine whether any of these trials will prove efficacious, but accumulating data from >100 MSC clinical trials (mostly phase 1 or 2) registered on clinicaltrials.gov for treating diseases affecting other organs suggest that, at least for MSCs, there appears to be little safety risk to participants.[127] There is also little reason to believe that these trials will result in regeneration of lung tissue for participants, as the bulk of basic mechanistic studies in animals suggest the infused cells work mostly via paracrine or immunomodulatory effects on recipient lung tissue, as detailed above.[46] Thus, these trials might be viewed as evaluations of cell-based immunomodulatory drug delivery rather than attempts to regenerate lung tissue.[128] Infused endothelial progenitor cells (EPCs), which are investigated as a potential treatment for pulmonary hypertension, also appear to have paracrine and perhaps angiogenic effects on recipient tissue,[46] but their capacity to directly form replacement endothelial cells in the lung remains in doubt. When viewed with these results in mind, the term "stem or progenitor cell"—used to refer to the cells being infused in the trials to date—risks misleading clinicians and participants attracted by the promise that these terms imply. The dream of delivering truly regenerative or reconstituting cells to the lung, such as endogenous lung progenitors, ESCs, or iPSCs, will need to be appropriately delayed while these cell populations are fully evaluated in laboratory animals. The impressive differentiation and proliferation potential of the newly described PSC-derived populations also makes them potentially risky and teratogenic in human trials, if deployed before their biology is more fully understood.

All indicators suggest that we are at the onset of realizing the promise of lung regenerative medicine propelled by the quickening pace of stem cell research. Endogenous lung stem or progenitor cell populations, such as basal cells, are already revealing the mechanisms that control their biology in careful studies at the lab bench.[42,44,66,129–131] New bioartificial lungs generated in the laboratory have already been successfully transplanted into rat recipients,[84,85] and human iPSCs generated from patients with alpha-1 antitrypsin (AAT) deficiency have undergone successful gene correction in vitro followed by hepatic transplantation into rodents.[132] Early studies of approaches for transplanting epithelial progenitors into animal lungs following injury[60,62,76–82] also imply that a similar approach may one day be feasible for reconstituting the lung epithelium by transplantation of gene-edited lung progenitors derived from either iPSCs or endogenous sources.

How will the emerging studies focused on lung stem cells impact future clinical care of patients with lung disease? Treatment approaches are likely to involve one or more of several approaches based on the growing literature on endogenous lung progenitors and the recently described lung lineages developed from exogenous PSC sources, such as iPSCs. First, an improved understanding of the pathways that regulate endogenous lung progenitors and control their cell fate decisions to self-renew or differentiate is likely to result in pharmaceutical approaches designed to regulate the behavior of these cell populations during disease pathogenesis. For example, if syndromes such as bronchiolitis obliterans result from an inability to maintain bronchiolar epithelial homeostasis, then an improved understanding of the biology of progenitors of the airways should with time lead to drug approaches for regulating the behavior of these cells toward improved maintenance of homeostasis, epithelial–mesenchymal crosstalk, or epithelial barrier integrity. Second, gene therapies aimed at correcting monogenic lung diseases, such as cystic fibrosis or alpha-1 antitrypsin deficiency, likely will involve gene editing[61] or gene correction of lung progenitors or stem cells. A key hurdle limiting progress in lung gene therapy has been the inability to accomplish gene transfer into enough cell numbers. Stem cells provide a potential solution to this problem, since correction of just one stem cell may be sufficient if that cell can self-renew (either in vitro or after engraftment in vivo) extensively enough to reconstitute large numbers of lung epithelial cells via its progeny. Hence, methods for the translation of the aforementioned mouse transplantation therapies to humans will be required in order for this hope to come to fruition.

iPSCs are likely to impact lung disease treatments in several ways in the future. First, personalized therapeutic drug regimens can be screened in vitro using lung lineages derived from each patient's iPSCs, potentially predicting effective individualized drug regimens for each individual, rather than the globalized approach currently used to treat disease, where treatments for disease targets are chosen based on trial data from heterogeneous cohorts of patients. If approaches for engrafting or reconstituting human lung tissue with exogenously delivered cells are ever successfully developed, iPSC-derived cells are one potential source of autologous cell derivatives for potential reconstituting therapies. A particularly attractive, yet far-off, goal of some stem cell researchers is the engineering of tissues from stem cells, including the tissue engineering of a whole, functioning, transplantable lung.[84,85] Several groups are working to optimize this approach using iPSCs to derive lung lineages for recellularizing these grafts to optimize tissue engineering of bioartificial lungs for transplantation in the future.

While some prospects for employing stem cell–based therapies will take many years to come to fruition, this exciting field of research raises many potential avenues for achieving the long-sought goal of lung regenerative therapies. Perhaps at this, the most optimistic time in a century of basic science research, we would be most wise to re-emphasize that many of the miraculous advances being made in this field are based on basic science research discoveries realized by investigators who originally had no practical clinical translation in mind. Those who simply wondered what made the Drosophila fly's wing notched, or made the jellyfish glow green, for example, paved the way for today's stem cell discoveries. In 1976, Comroe and Dripps found that the top 10 clinical advances in cardiac and pulmonary medicine derived from 529 key articles, 61.7%

of which were classified as "basic science research" and 42% were not clinically oriented at the time the work was done, leading the authors to conclude that "basic science research" pays off in terms of key discoveries.[133] Their report from 45 years ago potentially provides a guide for realizing the full promise of lung-related stem cell research in the years ahead.

SUMMARY

Research discoveries in the fields of stem cell biology and regenerative medicine are beginning to advance and refine an understanding of lung injury and repair. While these emerging studies offer unprecedented opportunities to develop novel therapies for a variety of lung diseases, realization of these therapies will take time and clinical application remains predominantly a future prospect rather than a clinical trial–ready treatment. Given the increasing number of questions from patients about how stem cell research will impact their care, this chapter provides an overview for the clinician or clinician-researcher of the latest advances in lung-related stem cell research and places the new discoveries in a historic context. Established, lineage-restricted, epithelial progenitors of the conducting airways and gas-exchanging alveoli are briefly reviewed, and controversial, newly proposed, tissue-specific candidate lung stem/progenitor cells with broader differentiation repertoire are introduced. Exogenous derivation of lung epithelia from ESCs or iPSCs is also presented as an alternative method for engineering lung tissue de novo in culture.

CHAPTER 9

Personalized Pulmonary Medicine

Benjamin A. Raby
Kelan G. Tantisira

INTRODUCTION

Since the first draft sequences of the human genome were completed in 2001,[1,2] medical research has increasingly focused on the utilization of genetic and genomic profiling in the prediction of disease susceptibility and natural history, as well as drug response and drug development. Personalized medicine, aka "precision" medicine, can be defined as an approach to medicine in which medical decisions are tailored to the individual patient. In theory, in patients with established disease, personalized medicine will make health care more efficacious, more affordable, and safer by avoiding costly and prolonged trial-and-error approaches, unwanted therapeutic side effects, and diminished treatment efficacy. In preclinical settings where an individual's molecular profile could be used to estimate their risk of disease, precision medicine can be used to triage patients for more vigilant screening to identify disease presence before clinical indications and symptoms appear or to initiate preventative therapies. Thus, personalized medicine enhances the focus on preventive medicine at the primary, secondary, and tertiary levels. Fully realized, personalized medicine has the potential to facilitate early diagnosis and/or prevention of disease and selection of optimal therapeutic choices with minimal attendant side effects for established disease states. The potential benefits, from both a financial and quality of life perspective, are enormous.

Much of the efforts to adopt personalized medicine into clinical practice have centered on genetic approaches, as sequence changes in deoxyribonucleic acid (DNA) have been closely associated with a wide range of disease susceptibilities and therapeutic responses. However, the "omics" era includes enhanced focus on cellular and metabolic changes downstream of DNA sequence variation including genomics or transcriptomics (the analysis of gene expression), proteomics (the analysis of protein changes), and metabolomics (the analysis of end products of cellular metabolism). Adding to genomic complexity are the so-called epigenetic changes, the study of changes in gene expression or cellular phenotype caused by mechanisms other than changes in DNA sequence, such as DNA methylation, post-translational modification of gene expression, and microRNA (see Chapter 7). Many of these modalities are already being used as biomarkers in a personalized medicine context, and all have the potential to do so. In this chapter we review the foundations of personalized pulmonary medicine and the current approaches being used to develop personalized diagnostic and treatment strategies for pulmonary disorders, including specific examples of personalized approaches currently being implemented in clinical practice. We provide overviews of human genetics, personalized pulmonary diagnostic testing, pharmacogenomics, biomarkers, and future implementation as they relate to personalized respiratory medicine.

DETERMINANTS OF THE CLINICAL UTILITY OF A GENETIC TEST

The predictive power of a genetic test is a function of four interdependent estimable parameters: (1) the *heritability* of the trait; (2) the *penetrance* of the tested genetic variant; (3) *allelic heterogeneity*; and (4) the variant *allele frequency*.

Heritability can be defined as the proportion of disease risk that is explained by genetic determinants. Heritability is highest (~100%) among monogenic diseases like cystic fibrosis, and more modest (30%–60%) for common diseases such as asthma or obstructive sleep apnea, where a substantial proportion of disease risk is due to environmental factors. The heritability for many commonly measured pulmonary quantitative traits is also modest (Table 9-1).

Penetrance is defined as the likelihood of manifesting phenotype (i.e., disease or trait) among individuals who carry the risk genotype (Fig. 9-1). Penetrance is highest for variants implicated in rare monogenic disorders, approaching 100% for the ΔF508 mutation in cystic fibrosis (CF) and is lowest for more prevalent genetic variants associated with common diseases. The range of reported penetrance in pulmonary disease is broad, from 90% for FLCN mutations in Birt-Hogg-Dubé syndrome (BHD)[3] to 20% to 50% for *BMPR2* mutations in familial pulmonary hypertension[4] and the *MUC5B* promoter polymorphism in familial pulmonary fibrosis.[5] Penetrance is phenotype-dependent. For example, in BHD, although ~90% of patients with *FLCN* mutations have radiographic evidence of parenchymal lung cysts, penetrance is lower for dermatologic findings (seen in ~60%) and spontaneous pneumothorax (observed in 38% of patients).[3] Similarly, although virtually all PiZ homozygotes have markedly reduced circulating levels of α1-antitrypsin levels, only a subset of these individuals manifests symptomatic emphysema.[6]

Allelic heterogeneity refers to the existence of more than one disease-causing allele at different locations in the same disease-causing gene. Although one variant may predominate as the most prevalent disease allele (for example, the Z allele in 85% in α1-antitrypsin deficiency), numerous pathogenic variants are typically described, including more than 20 *SERPINE1* mutations in α1-antitrypsin, 50 *FLCN* mutations in BHD, and more than 120 pathogenic *CFTR* variants in cystic fibrosis. Allelic heterogeneity must be distinguished from *locus heterogeneity*, where the same phenotype can manifest through mutations in different genes. For example, familial bronchiectasis resulting from primary ciliary dysfunction has been mapped to no fewer than 34 separate genes that code for distinct proteins of the ciliary apparatus.

TABLE 9-1 Heritability Estimates in Pulmonary Medicine

Trait	Heritability Estimates
Pulmonary diseases	
Cystic fibrosis	1.0
Asthma	0.36–0.72
COPD	0.40–0.77
Pulmonary fibrosis	
Sarcoidosis	0.60–0.70
Obstructive sleep apnea	0.33–0.52
Quantitative traits	
FEV_1	0.38–0.77
FVC	0.54–0.91
FEV_1/FVC	0.44–0.46
Airways responsiveness	0.30–0.66
D_{LCO}	0.39–0.46
IgE levels	0.40–0.60

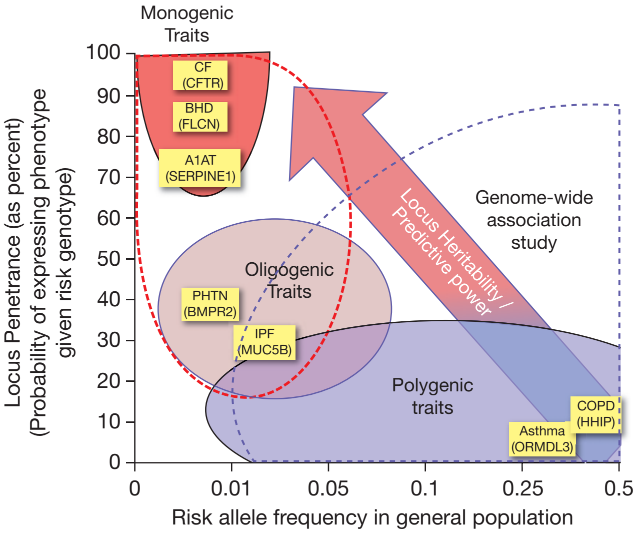

Figure 9-1 The relationship between allele frequency, locus heritability, predictive power, and genetic mapping strategies. Monogenic diseases, such as cystic fibrosis (CF), Birt-Hogg-Dubé syndrome (BHD), and α1-antitrypsin deficiency (A1AT) are caused by highly penetrant, deleterious causal mutations that can be detected by parametric linkage analysis. Polygenic, complex traits, such as asthma and COPD, are caused by numerous genes (dozens to hundreds) harboring variants of much weaker genetic effect. Genome-wide association studies can identify the subset of these variants, but their individual predictive value is low. Oligogenic traits, like familial forms of pulmonary hypertension (PHTN) and idiopathic pulmonary fibrosis (IPF), are caused by variants in a handful of genes with both intermediate frequencies and intermediate penetrance functions.

The influence of variant *allele frequency* on the predictive power of a genetic test is complex, and it depends largely on the strength of the genetic effect conferred (the locus heritability) and the disease prevalence. Rare monogenic lung diseases typically result from highly penetrant, low-frequency (<1%) variants situated in highly conserved protein-coding sequences. Most common disease susceptibility variants reported are of high frequency (>5% in the general population) but individually are of weak effect. In many instances, the population risk allele frequency exceeds the population disease prevalence (such as the asthma-associated *ORMDL3/GSDMB* risk haplotype, frequency of 62% in asthmatics). In these cases, the specificity of the variant is quite weak. In contrast, rare variants of high penetrance implicated in common disease will have high specificity, yet their low population prevalence diminishes their clinical predictive value, as sensitivity and negative predictive values will be poor.

GENETIC TESTING

All the major classes of genetic variation—including single nucleotide substitutions, insertions and deletions, copy number variants, and larger, more complex structural variants—have been described in pulmonary disease (Table 9-2), and no single technology has been developed that can reliably survey all these forms simultaneously. The rapid pace of technological advancement and the vast number of technologies in current use preclude comprehensive review of all available genetic diagnostic platforms here. Instead, we focus on next-generation sequencing, which is emerging as an efficient, reliable, and increasingly affordable diagnostic platform in many clinical contexts.

■ Whole-Genome Sequencing

Next-generation sequencing (NGS) platforms enable DNA sequencing in a highly paralleled fashion by generating short sequence reads (30 to 135 bases in length) sampled randomly from across the target sequence. With these methods, sequencing of nearly all genomic regions (i.e., "whole genome") is now feasible and is being widely implemented for both research and clinical purposes. The massive parallel nature of these techniques, and their lack of reliance on Sanger chemistries, have resulted in dramatic reductions in cost (now less than $1000) for whole-genome sequence.

The major technical challenge, and an important determinant of cost, is achieving sufficient base-calling accuracy. Given the very large numbers of both the bases being called (billions) and polymorphisms per genome (~3–4 million), accuracies of >99.9% are needed to limit the number of spurious findings (both false positive and negative). Such accuracy can be achieved by ensuring high read depth—the number of times a given base is sequenced. For clinical purposes, minimum average read depths of 30–40 times provide reasonable accuracies. For whole genomes, such coverage can be achieved only by performing multiple sequencing runs, increasing costs considerably. Despite this, however, the more expensive elements of whole-genome sequencing are the downstream data analysis costs, which include sequence quality assessment, sequence alignment and annotation, and variant classification (see below).

Additional costs are often incurred from the current clinical guidelines that mandate independent technical validation of all actionable (clinically relevant, reportable) variants by Sanger sequencing. Thus, while the technical cost continues to fall, current total charges (often exceeding $10,000 per clinical genome) have limited widespread adoption of whole-genome sequencing at present. Moreover, because all people carry thousands of functional variants, many of which are disease causing, physicians ordering whole-genome sequence should anticipate identifying incidental findings (including unsuspected actionable variants in genes unrelated to pulmonary disease) of which the patient would need to be informed. Thus, we recommend judicious use of whole-genome sequencing, with appropriate pretest counseling with the assistance of an experienced provider and genetic counselor.

■ Targeted Sequencing Panels

While use of whole-genome sequencing in clinical practice remains modest, there is increasing use of focused, targeted NGS of selected genes or gene regions, which is achieved by "pulling down" DNA segments of interest using oligonucleotide filters (i.e., probe sets that bind complementary sequence). These filters can be customized to target specific sequences, ranging from a handful of genes to all gene-coding regions (i.e., whole exome filters). This approach markedly reduces the size of targeted sequence length (for example, an exome sequence is only 3% of the total genome sequence), with numerous advantages for clinical implementation. The marked reduction in target size accommodates clinically reliable read depths in one sequence run, reduces analytic costs (as there is less sequence to annotate), and reduces follow-up validation costs. Panel testing also sharply limits the potential for incidental findings, greatly simplifying both pre- and posttest counseling.

■ Pulmonary-Specific Sequencing Panels

Targeted sequencing panels of selected genes that cause pulmonary disease are available commercially through several companies and clinical laboratories. The services provided differ from each other primarily in their gene content, which are frequently organized in discrete gene panels. Most panels are designed to assess limited sets of genes implicated in disorders typified by a particular clinical or radiographic manifestation (i.e., a pulmonary fibrosis panel) or a shared molecular defect (i.e., ciliopathy panel). The largest panels available are those for workup of pulmonary fibrosis and bronchiectasis. Due to technical limitations and the constant pace of novel disease-gene discovery, few

TABLE 9-2 Types of Genetic Variation and Their Relative Contribution to Disease Phenotype

Genetic Variation	Definition	Phenotypic Variation %[a]	Example	Pulmonary Manifestation
Chromosomal abnormalities				
Numerical abnormalities	Variations in chromosome number			
Polyploidy	Additional genome copies		69 XXY	Fetal loss
Aneuploidy	Variable number of single chromosome	<1%	Trisomy 21: Down syndrome	Obstructive sleep apnea and pulmonary hypertension
		<1%	Monosomy XO: Turner syndrome	No common pulmonary phenotype
Structural abnormalities	Variations in chromosome structure			
Gross rearrangements	Visible by karyotype/FISH	1%	del(4)(q12): FIP1L1-PDGFRA gene fusion	
Translocations	Aberrant exchange of DNA sequence between two different chromosomes		T(9;22)—Philadelphia chromosome of chronic myelogenous leukemia	Somatic translocations commonly seen in lung cancer tumors
Inversions	Altered sequence orientation		900-kb inversion on 17q21	Glucocorticoid pharmacogenetic response
Copy number variants	Gains or losses of DNA sequence spanning 500 bp or more	9%	GSTM1 null variant	Smoking-related lung function decline
Sequence variants				
Single nucleotide polymorphism	Single base pair substitutions			
Nonsense/missense	Variant introduces stop codon/amino acid substitution	55%	FLCN R4496X: Birt-Hogg-Dubé SERPINE1 Glu366Lys (Z) allele	Spontaneous pneumothorax, α1-antitrypsin deficiency, emphysema
Splicing	Variant alters normal intron splicing pattern	9.20%	DNAI1 IVS1+3insT: Primary ciliary dyskinesia	Bronchiectasis
Regulatory	Variant alters mRNA transcription or protein translation	2%	17q21 rs12936231 variant alters ORMDL3/GSDMB expression	Asthma
Insertion/deletion (Indel)	Gain or loss of one or more nucleotides	23%	CFTR ΔF508	Cystic fibrosis
Short tandem repeat	Repetitive element that varies in copy number	0.30%	PHOX2B exon 3 polyalanine repeat expansion	Primary central hypoventilation syndrome

[a] *Percent of total variation listed in Human Gene Mutation Database (http://www.hgmd.cf.ac.uk/ac/), accessed May 30, 2013.*

panels can be considered fully comprehensive. Yet, most offer coverage of the most commonly implicated genes being considered clinically. Even for large panels (40 or more genes), the costs of panel sequencing are comparable to those of other genetic tests routinely used in practice (cytogenetics) and typically only 2–3 times the cost of single-gene sequencing. Thus, when more than one gene is clinically suspected, or for diseases with known locus heterogeneity, diagnostic panels offer greater sensitivity and cost efficiency over single gene testing.

More broad sequencing panels may have particular value in the evaluation of patients with more complex presentations (for example, patients presenting with a combination of bronchiectatic and fibrotic features, or with parenchymal lung disease disproportionate to the degree of concomitant pulmonary hypertension). When a genetic basis is suspected, massively paralleled sequencing across multiple disease panels may help narrow the differential diagnosis to one or two disorders. One such solution, available through some sequencing providers, is a sequential, hierarchical analysis approach, where analysis/interpretation of a whole exome sequence is initially limited to the panel deemed most likely to harbor mutation and then extended to increasingly less probable panels (and eventually whole exome) as needed. For example, evaluation of idiopathic bronchiectasis may begin with a bronchiectasis panel (∼40 genes, including CFTR, PCD genes, and SERPINA1), with reflex testing of immunodeficiency panels (often greater than 150 genes). Although possibly more cost-effective over current diagnostic strategies, the value of such an approach to the workup of patients with complex presentations remains unclear.

■ Interpreting Genetic Test Results

The American College of Medical Genetics has developed guidelines for the classification of variants based on their probability of pathogenicity.[7] This classification schema and the criteria for variant classification (Table 9-3) have been broadly adopted by clinical laboratories and are included routinely in test reports. There are five variant categories: “pathogenic,” “likely pathogenic,” “variant of unknown significance (VUS),” “likely benign,” and “benign.” Variants classified as pathogenic are those firmly implicated as disease-causing due to their demonstrated functional impact, their localization to a highly conserved functional genomic sequence, their presence in affected individuals only, and their strong segregation with disease. Likely pathogenic variants have many, but not all, of these features. Benign variants are those that are common

TABLE 9-3 American College of Medical Genetics Standards and Guidelines for Variant Reporting

	Strength of Evidence (Odds of pathogenicity[a])					
	Benign			Pathogenic		
	Strong (−18.7)	Supporting (−2.08)	Supporting (2.08)	Moderate (4.33)	Strong (18.7)	Very Strong (350.0)
Population allele frequencies	High allele frequency/ presence in controls inconsistent with penetrance			Absent in databases	Prevalence in cases > controls	
Computational and predictive analysis		Multiple lines of evidence support benign effect Missense variant in gene with only disease-causing are LOF	Multiple lines of evidence support deleterious effect	Missense in gene with other missense/ truncating	Same amino acid change	Null variant in gene where LOF is pathogenic
Functional studies	Studies show no deleterious effect		Missense in gene with low missense rate	Mutational hot spot in well-studied functional domain	Studies confirm deleterious effect	
Segregation in families	Segregation in healthy individuals		Co-segregation with multiple affected individuals	⟶	Increasing segregation data ⟶	⟶
De novo				De novo (paternity uncertain)	De novo (paternity certain)	
Allelic information		Observed with pathogenic variant		For recessive disease, found in trans with pathogenic variant		
Other databases		Reputable source	Reputable source			
Other		Found in cases with alternate cause	Phenotype or family history highly specific for gene			

[a]As reported by Strande et al.[109] Assumes a prior probability of 0.10 for a single-gene analysis.

Reproduced with permission from Richards S, Aziz N, Bale S, et al. Standards and guidelines for the interpretation of sequence variants: a joint consensus recommendation of the American College of Medical Genetics and Genomics and the Association for Molecular Pathology, Genet Med. 2015;17(5):405–424.

among healthy controls, have no demonstrable function, and do not segregate with disease in families. Counseling of patients regarding these three classes of variants is often unambiguous: the finding of pathogenic or likely pathogenic variants in a gene known to cause phenotypes consistent with those of the patient often confirm or establish diagnosis and can inform management decisions, while finding only benign variants can, in the appropriate clinical context, provide reassuring information by excluding specific disorders. In contrast, VUS variants fall into a grey zone: either they do not have a sufficient number of features to firmly classify in one category, or they meet criteria for both benign and pathogenic that are contradictory. Given that most disease-causing variants are rare (often private to one family or ethnic group) and are thus unlikely to have been studied experimentally for functional impact or disease association, the likelihood of detecting a VUS is high and increases as the number of genes tested is increased. Providers and patients must understand the possibility of such findings and their implications on subsequent workup and management.

■ Clinical Indications for Genetic Testing

Table 9-4 lists the most common uses of genetic information in clinical practice, for both the patient and at-risk family members. Diagnostic genetic testing is of greatest value when knowledge of the specific gene or mutation will directly impact clinical management. In these cases, genetic testing should be offered to patients in whom the possibility of defining an actionable variant is high, including those with specific disease presentations compatible with the diagnosis of interest, at-risk family members of patients with confirmed molecular diagnoses, and subjects with strong family histories. Examples include:

- Confirmation of α1-antitrypsin deficiency in patients with emphysema and lung function decline identifies a small subset of COPD patients who may benefit from replacement therapy.
- Characterizing CFTR genotypes in patients with cystic fibrosis to determine likelihood of responsiveness to modulator therapy.[8,9]
- Differentiating molecular forms of familial idiopathic pulmonary fibrosis: (1) Patients with *SFTPC* mutations may benefit from hydroxychloroquine treatment;[10] (2) TERC and TERT mutations help identify patients with short telomere syndrome (STS) at risk of marrow and liver failure, including during the post–lung transplant period; (3) Hermansky-Pudlak syndrome (HPS) can often be overlooked clinically due to subtle neurologic (nystagmus) and dermatologic (albinism) features, although these patients are at risk for a potentially severe but treatable (with DDAVP) bleeding diathesis.

TABLE 9-4 Utility of Genetic Information in Clinical Practice

Activity	Paradigmatic Example	Current/*Potential* Utility in Pulmonary Medicine
Preimplantation screening	Tay-Sachs disease	*Primary ciliary dyskinesia*
In utero diagnosis	Trisomy 21	*Congenital diaphragmatic hernia*
Newborn screening	Phenylketonuria	Cystic fibrosis
Diagnostics		LAM versus Birt-Hogg-Dubé syndrome
Prognostics	Expansion length and age of onset in Huntington's disease	*MUC5B as positive prognostic in IPF*
Presymptomatic interventions	BRCA1 and prophylactic mastectomy/oophorectomy	*BMPR2 and vasodilator therapy*
Surveillance strategies	APC mutations and familial adenomatous polyposis	FLCN mutations and renal cancer screening in Birt-Hogg-Dubé syndrome
Replacement therapies	Gaucher's disease	A1-antitrypsin deficiency
Mutation-directed therapies	Tyrosine kinase inhibition in EGFR+ tumors	Ivacaftor in G551R-positive cystic fibrosis
Pharmacogenetics	Warfarin dosing	*Polygenic model of inhaled corticosteroid response in asthma*
Gene replacement therapy	X-linked severe combined immunodeficiency	*Surfactant gene replacement in infantile pulmonary fibrosis*

For highly penetrant monogenic diseases, the implications of a positive test result are often profound, even in instances where gene- or mutation-specific therapies are not yet available. Examples include preclinical identification of patients at risk for malignancy (for example, in BHD or LAM), accelerated lung function decline (in LAM, familial fibrosis), cerebrovascular complications (in hereditary hemorrhagic telangiectasia), or pulmonary hypertension, who can be more closely followed enabling earlier intervention, and who can be more vigorously counseled regarding the benefits of tobacco smoke avoidance or other risk modification. An illustrative example is provided in Fig. 9-2, depicting the value of testing in a family pedigree with BHD. For autosomal dominant diseases of variable penetrance, and for recessive disease, genetic testing offers the ability to identify at-risk carriers prior to the onset of symptoms, providing opportunities for early diagnosis.[11] Negative test results are also of value, providing reassurance to relatives that they are not at risk of developing an illness they may have witnessed afflicting their relatives.

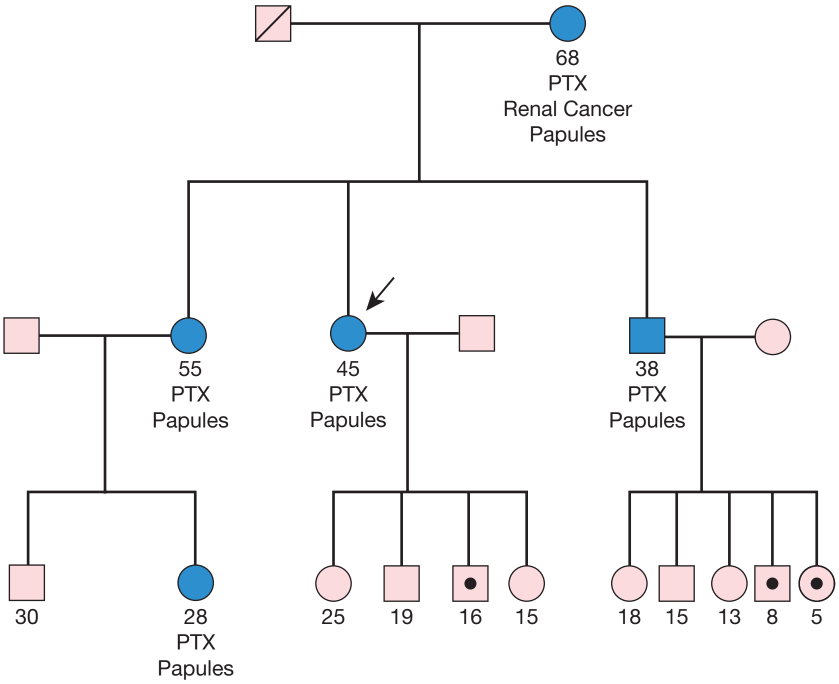

Figure 9-2 Birt-Hogg-Dubé (BHD) syndrome. Index patient (*arrow*) confirmed to harbor a pathogenic FLCN gene mutation. The maternal history of renal cancer places other mutation carriers in this family at risk of both renal and other malignancies. In this pedigree, the large number of reportedly unaffected offspring of two carriers is unusual, given a 50% probability of transmission from carrier to offspring. More likely, the mutation was passed on (hypothetically denoted by dot), but these carriers have not yet developed clinical manifestations, possibly due to their younger age. Such individuals would be at risk of eventually developing BHD, including malignancy. Therefore, confirmation of carrier status among at-risk, but seemingly unaffected, family members is warranted.

■ Genetic Counseling in Pulmonary Medicine

The inherently predictive, personal, and irreversible nature of an individual's genetic code distinguishes genetic from other forms of clinical testing. The psychological impact of genetic test results, whether positive or negative, cannot be underestimated. Feelings of inadequacy or imperfection, a sense of inevitable doom, and therapeutic nihilism due to a genetic "fate" are not uncommon with a confirmed genetic diagnosis. Conversely, negative results can lead to a false sense of invincibility, leading to unhealthy behaviors (for example, continuing to smoke). Inherently, the potential impact of genetic testing extends beyond the patient, implicating all blood relatives. Moreover, test results can impact family dynamics and the way in which individual family members react to their test results. For example, although most at-risk family members will be relieved by a negative test result, some experience a deep sense of guilt ("survivor's guilt") in relation to their affected family members. In addition, despite legislation at state and federal levels protecting patients from genetic discrimination in the workplace and in access to health care insurance, patients must be informed regarding this risk in other contexts (for example, the impact on eligibility for life insurance policies). Lastly, we emphasized that, prior to ordering expansive tests (panels, exomes, genomes), patients must be made aware that broad surveys increase the likelihood of identifying variants of unknown clinical significance (so-called VUS). Patients must be counseled pre-test regarding the uncertainty these findings may impart.

For all these reasons, it is advised that expanded genetic testing be offered only by, or in consultation with, experienced providers familiar with these issues, including certified genetic counselors, who can adequately address the medical, psychological, and familial implications of test results. We recommend initiating these discussions prior to testing ("pretest counseling"), so that patients are empowered to provide truly informed consent. Patients should be made aware of the medical implications of both positive and negative results and should be advised regarding the impact these results may have on them and their family members. Genetic pretest counseling should also address the potential identification of variants of unclear significance, as well as the potential impact of positive test results on both the cost of, and eligibility to obtain, life or long-term disability insurance. This approach can mitigate the development of patient stress and regret, even when returning potentially distressing results.[12]

MUTATION-SPECIFIC THERAPIES IN MONOGENIC LUNG DISEASE

One of the primary goals of genetic classification of disease is the development of mutation-specific treatment strategies. Such activities have traditionally focused on the development of replacement therapies for loss-of-function recessive diseases (e.g., recombinant human α1-proteinase inhibitor replacement therapies for α1-antitrypsin deficiency). Newer pharmacologic approaches, including small molecule screens and others informed by the functional impact of specific mutations, are emerging.

Tyrosine Kinase Inhibition for Hypereosinophilic Syndrome

Imatinib was identified as a therapy for chronic myelogenous leukemia (CML). However, once the functional mechanisms underlying its therapeutic effects were elucidated other therapeutic indications were identified, including its use in the treatment of hypereosinophilic syndrome (HES). Subsets of HES patients harbor a chromosome 4q interstitial deletion that results in the creation of a fusion of the *FIP1L1* and *PDGFRA* genes. The resultant fusion protein has tyrosine kinase activity similar to that of the BCR-ABL fusion protein in CML (the target of imatinib), and HES patients positive for the *FIP1L1-PDGFRA* rearrangement respond positively to imatinib therapy.[13,14] *FIP1L1-PDGFRA*-negative HES patients do not. Similar to CML, mutations of the tyrosine kinase binding site have been reported upon HES relapse.

Mutation-Specific Therapies for Cystic Fibrosis

In 2011, positive results of a randomized clinical trial of a novel therapy for G551D-positive cystic fibrosis were reported[8] (Fig. 9-3). This oral agent—ivacaftor—"potentiates" CFTR activity by prolonging channel opening times and augmenting transmembrane chloride transportation in individuals with class III CFTR mutations, the most common of which is G551D. In a randomized, double-blind, placebo-controlled trial, cystic fibrosis patients with at least one G551D mutation treated with ivacaftor demonstrated significant improvements in FEV_1, fewer respiratory exacerbations, improved quality of life, and a positive weight gain compared with those receiving placebo. The ~50% reduction in sweat chloride levels to those approaching those observed in asymptomatic *CFTR* mutation carriers (i.e., heterozygotes) serves as an elegant molecular-clinical correlate, suggesting selective effect on the G551D+ channel, but not ΔF508+ channels. Class III mutations are found in only ~6% of patients. Subsequently, two additional compounds have been developed that improve function of other CFTR channel classes, including ΔF508 and ~90% of all CF-causing variants. The efficacy of combined triple therapy (elexacaftor-tezacaftor-ivacaftor) was established in two large, randomized, placebo-controlled trials that demonstrated clinically significant improvements in lung function and quality of life and marked reductions in exacerbation and hospitalization rates (Fig. 9-3D). The advent of this novel treatment strategy provides motivation for the development of additional agents that target other *CFTR* mutation classes (including the most common *CFTR* mutation—ΔF508) and the application of similar strategies for the treatment of other genetic diseases. This example also illustrates the increasing importance of classifying patients by genotype status, as there remain 10% of CF patients—those with mutations that preclude CFTR protein production (class I mutations)—who are not responsive to triple therapy. Alternative approaches to address these patients' needs are in development, including the prospect of so-called read-through therapies.

INTRODUCTION TO DIAGNOSTIC TESTING

Given the increase in biomarkers with an emphasis on precision medicine, a brief review of quantifiable diagnostic measures of accuracy is warranted. Importantly, poorly designed studies, or studies limited to a specific disease stratum or subgroup, may generate false estimates of the test accuracy or severely limit generalizability of the results. The classic metrics of diagnostic accuracy as it applies to the patients receiving the test include sensitivity, the proportion of disease subjects with a positive test (TP, see Table 9-5) in a total group of subjects with the disease: TP/(TP + FN). Sensitivity thus represents the probability of getting a positive result in a patient with the disease and relates directly to the ability of a test to recognize the ill, i.e., the true positive rate. Specificity is the proportion of subjects without the disease with a negative test result (TN) in a total group of subjects without the disease: TN/(TN + FP). That is, specificity represents the probability of getting a negative test result in a healthy subject (i.e., the true negative rate); it relates to the ability of a diagnostic procedure to recognize the healthy. In the ideal world, every diagnostic test would have a sensitivity and a specificity of 1.0 (100%), but no test is perfect. While sensitivity and specificity are not dependent on disease prevalence, their discriminative ability may increase with disease severity. When combined and plotted for different values of sensitivity and 1–specificity (one minus specificity), these two measures generate a receiver operator curve (ROC), in which the area under the ROC curve (AUROC) can vary from 0.5 (no discriminatory ability) to 1.0 (perfect diagnostic test).

While sensitivity and specificity are informative with regard to using patients with known disease to comment on test accuracy, often the clinical question centers around the converse, "How certain can we be about the disease status of a subject given a positive (or negative) test result?" To answer this question, predictive values are used. Positive predictive values (PPV) represent the proportion of diseased patients with a positive test result in a total group of subjects with a positive result: TP/(TP + FP) (see Table 9-5), whereas negative predictive values (NPV) are defined as the proportion of subjects without the disease and with a negative test result in a total group of subjects with a negative test result: TN/(TN + FN). Notably, both PPV and NPV depend on disease prevalence, with PPV increasing and NPV decreasing with an increase in the prevalence of a disease in a given population.

Currently, the most pervasive biomarker tests directly related to pulmonary medicine are the ones linked to COVID-19, which makes for an interesting use case scenario. More than 160 COVID-19 tests

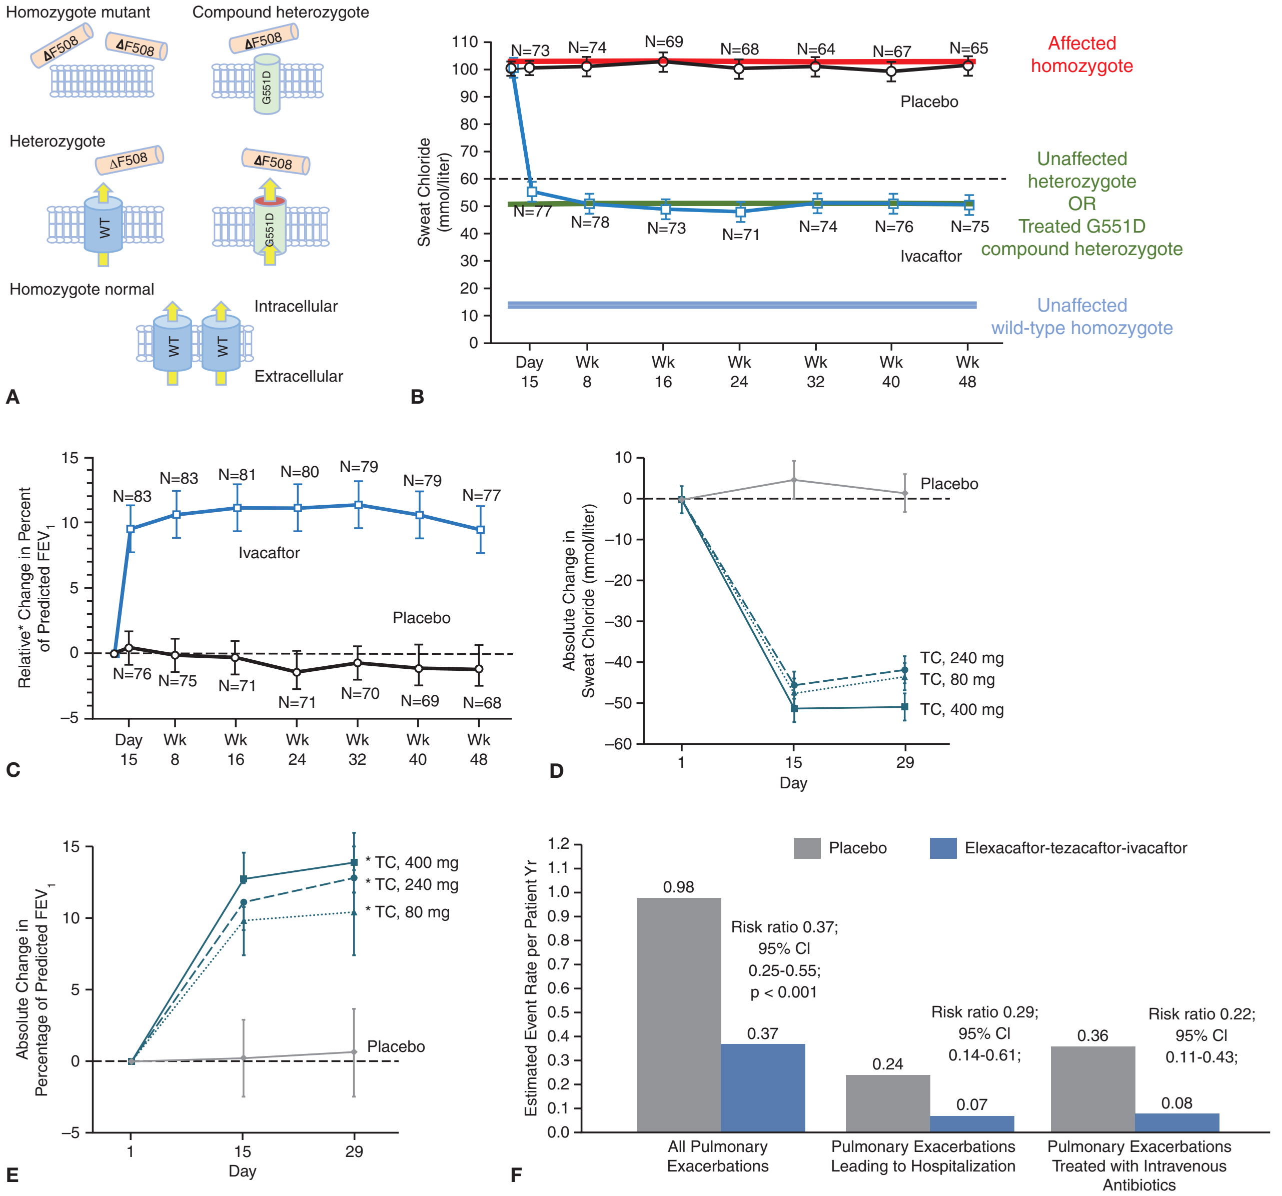

Figure 9-3 Mutation-specific therapeutic action of CFTR modulators in cystic fibrosis. **A, B.** The additive effect of CFTR mutations on epithelial chloride efflux and sweat chloride levels, and the effect of ivacaftor. Individuals with 2 normal alleles have normal chloride efflux (yellow arrows), and a corresponding normal sweat chloride test (blue double line). Individuals with two mutated alleles demonstrate markedly reduced chloride efflux and elevated sweat chloride (red line). Heterozygotes with ~%50 normal functional chloride channels on epithelial cell surfaces manifest intermediate reductions in both chloride efflux and sweat chloride responses (orange line). G551D compound heterozygotes treated with ivacaftor (red disc) demonstrate sweat chloride levels similar to heterozygote carriers. **C.** Therapeutic efficacy of ivacaftor: Patients randomized to ivacaftor demonstrated improvements in relative change in percent of predicted FEV_1 over 48 weeks, in addition to improvements in body weight, symptoms and in quality of life scores (not shown). (Original report erroneously labeled figure as absolute [not relative] change in percent of predicted FEV_1.) **D–F.** Therapeutic efficacy of triple modulator therapy: Panels **D** and **E** demonstrate improvements in sweat chloride and absolute change of FEV_1 over 29 days in patients randomized one of three doses of triple therapy compared to placebo. Panel **F** demonstrates clinical meaningful reductions in all pulmonary exacerbations (63% reduction), those leading to hospitalization (71% reduction), and those treated with intravenous antibiotics (78% reduction) among those treated with triple therapy compared to placebo. *(**B** and **C** Reproduced with permission from Ramsey BW, Davies J, McElvaney NG, et al. have been authorized in the United States.[15] While there is no "gold standard" for test performance, estimates of sensitivity have been made, with one study reporting sensitivities of 32%, 63%, 72%, and 93% for throat swabs, nasal swabs, sputum, and BAL fluid, respectively.[16] Given that these sensitivities were reported in hospitalized populations at high risk, sensitivities in the community setting are likely far lower. One meta-analysis demonstrated an overall sensitivity of 70% and specificity of 95% for RT-PCR test performance.[17] A second meta-analysis, limited to respiratory sampling in symptomatic patients, demonstrated an overall summary sensitivity

TABLE 9-5 Contingency Table for Diagnostic Testing

	Subject with Disease	Subject Without Disease	Total
Test—positive	TP	FP	TP + FP
Test—negative	FN	TN	FN + TN
Total	TP + FN	FP + TN	

TP, true positive; FP, false positive; FN, false negative; TN, true negative.

of 89.1% (95% credible interval [CR], 84.0–92.7) and specificity 98.9% (95% CR, 98.0–99.4).[18] Finally, a recent Cochrane review noted that SARS-CoV-2 diagnostic testing varied considerably across studies and test type.[19] For antigen tests the sensitivity varied from 0% to 94%; the average sensitivity was 56.2% (95% confidence interval [CI], 29.5–79.8) and average specificity was 99.5% (95% CI, 98.1–99.9 based on 8 evaluations in 5 studies on 943 samples). In contrast, the sensitivity of rapid molecular assays showed less variation compared to antigen tests (from 68% to 100%); for the rapid molecular assays, average sensitivity was 95.2% (95% CI, 86.7–98.3) and specificity 98.9% (95% CI, 97.3–99.5) based on 13 evaluations in 11 studies of on 2255 samples. Thus, different tests exhibit markedly different test characteristics.

Understanding of variability of test characteristics is clearly important in the care of patients. For instance, using the Cochrane data above (with a sensitivity of 95% and specificity of 99%), a hypothetical cohort of 1000 people with suspected COVID-19 infection (with a prevalence of 10%) would be predicted to result in 105 positive test results including 10 false positives (positive predictive value 90%), and 895 negative results including 5 false negatives (negative predictive value 99%). Incumbent on the pulmonary practitioner is the additional knowledge of how a higher prevalence (or pretest likelihood) for a presenting individual or a lower prevalence for a susceptible larger population may be have substantial implications related to test interpretation. For example, a busy emergency room physician who develops fever, cough, and fatigue following a run of local SARS-CoV-2 infections has an initial COVID-19 negative test. However, given a pretest likelihood of disease of 90%, with a test specificity of 95%, that physician still has a 74% chance of having COVID-19.[20] In contrast, if one tests a large metropolitan area of 5 million people with a disease prevalence of only 1% and a COVID-19 test with 98% sensitivity and 99% specificity, 1000 SARS-CoV-2 positive cases would be missed (false negative), increasing the risk of spread, and 49,500 people would receive false positive results, potentially burdening the public health system.[15]

BIOMARKERS IN PULMONARY MEDICINE

Biomarkers have been defined as "biological characteristics that can be objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacological responses to a therapeutic intervention."[21] Ideal biomarker characteristics have been espoused (Table 9-6).[22] There are two major types of biomarkers applicable to clinical medicine: (1) biomarkers of exposure, which are used in risk prediction; and (2) biomarkers of disease, which are used in the screening, diagnosis, and monitoring of disease progression, as well as response to therapy. Thus, biomarkers have the potential to support clinical decisions, from diagnosis to treatment planning; to improve tailored treatment strategies; to avoid over- or under-treatment and adverse side effects; and to enhance prognosis and cost effectiveness.

While a number of biomarkers have been evaluated in a wide range of pulmonary conditions—including MMP-7, ICAM-1, and IL-8 for interstitial lung disease,[23] procalcitonin for community acquired pneumonia,[24,25] exhaled nitric oxide for asthma and other inflammatory lung disease,[26,27] and RAGE, ICAM-1, and SP-D for ARDS[28]—few are recommended for routine clinical use. This stems largely from their relatively weak predictive power. For instance, at a 5% false positive rate (specificity 95%), a relative odds of 3.0 between the 1st and 5th quartile of a biomarker gives only a 20% detection rate.[29] As a clinical example, a recent meta-analysis evaluating the value of procalcitonin for bacterial pneumonia in children yielded an overall sensitivity of 0.64 (95% CI, 0.53–0.74), a specificity of 0.72 (95% CI, 0.64–0.79), and an AUROC of 0.74 (95% CI, 0.70–0.78).[30] As such, this and other current biomarkers cannot directly substitute for other clinical parameters in clinical evaluation but can be used as adjuncts to support clinical judgment.

TABLE 9-6 Ideal Biomarker Characteristics

- Easy to measure
- Safe to measure
- Low cost to measure
- Consistent across gender, age, race
- Cost of follow-up tests is reasonable
- Proven therapy to modify biomarker
- Modification of biomarker is proven to protect against disease or outcome

An example of a biomarker in prominent routine use in pulmonary medicine is the D-dimer and its role in the diagnosis of acute pulmonary embolism (Fig. 9-4). The quantitative rapid enzyme-linked immunosorbent assay (ELISA) has a sensitivity of 95%. In patients with low pretest clinical probability (i.e., 4% to 15%), a normal D-dimer rapid ELISA substantially reduces the posttest probability of pulmonary embolism to 0.7%–2%.[31] Therefore, these

No treatment
Further tests
Further tests

Figure 9-4 Use of D-dimer as a biomarker in the exclusion of pulmonary embolism. The quantitative rapid enzyme-linked immunosorbent assay (ELISA), with a sensitivity of 95%, showed the most clinically useful values among the various D-dimer assays. When used in combination with a low probability objective clinical assessment, which ranges from 4% to 15%, the posttest probability of pulmonary embolism ranges from 0.7% to 2% with a normal D-dimer rapid ELISA. No further testing is required if D-dimer is normal in a patient with a low probability clinical assessment. *(Reproduced with permission from Stein PD, Woodard PK, Weg JG, et al. Diagnostic Pathways in Acute Pulmonary Embolism: Recommendations of the Pioped II Investigators. Am J Med. 2006;119(12):1048–1055.)*

patients can safely be excluded from further evaluation.[31–34] Notably, the D-dimer is still used adjunctively to clinical judgment, as both the predictive ability falls in patients with intermediate to high pretest clinical likelihood of pulmonary embolism and the relatively poor specificity (of about 27%)[35] of the D-dimer limit its usefulness outside of low probability cases.

More recently, pulmonary embolism guidelines have increasingly focused on using age-adjusted D-dimer cutoffs to assist with exclusion of pulmonary embolism, as D-dimer increases with normal aging.[36,37] One suggested modification is patient's age multiplied by 10 ng/mL for patients older than 50 years.[37]

The recent SARS-CoV-2 pandemic has seen an accompanying increase in the incidence of pulmonary embolism.[38,39] D-dimer admission levels, combined with D-dimer increment and fibrinogen, appears to have good prognostic ability for symptomatic pulmonary embolism cases (AUROC, 0.865; 95% CI, 0.822–0.907).[38]

PHARMACOGENETICS

The response to pharmacologic agents varies tremendously between individuals. For instance, the plasma level of a given medication can vary more than 1000-fold between two individuals having the same weight when treated with the same drug dosage.[40] On average for a given drug, 30% of patients show beneficial effects, 30% fail to improve, 10% experience only side effects, and 30% are noncompliant (which may be related to either lack of efficacy or side effects).[41] Therefore, as many as 70% of all patients are unnecessarily exposed to the potential to develop adverse drug reactions (ADRs).[42–44] In the United States, more than 2 million hospitalizations due to serious ADRs and more than 100,000 fatal ADRs were noted in 1994, ranking ADRs between the 4th and the 6th leading cause of death.[45] Worldwide, the prevalence of hospitalizations due to ADRs was recently estimated at a median of 5.3% (interquartile range [IQR], 2.7–9.0), as based on prospective cohort studies of more than 100,000 admissions.[46] Overall, the cost of drug-related morbidity and mortality in the United States exceeded $177.4 billion in 2000,[47] a figure more than double the estimate from 1995.[48] As enormous as these figures are, the burden due to lack of therapeutic response to drug therapy is likely to be much greater.[49]

Pharmacogenetics is the study of variability in drug response due to heredity. Pharmacogenetic variability in drug absorption, drug metabolism, and drug action at the receptor level is well known. Overall, it is estimated that genetics can account for 20% to 95% of variability in drug disposition and effects.[50] Ideally, pharmacogenetics will allow for "individualized therapy" based upon an individual's genetic makeup that will maximize the potential for therapeutic benefit, while minimizing the risk of adverse effects. The potential for cost savings and for decreasing morbidity and mortality is immense.

■ Pharmacogenetic Response Categories

The heritability of many therapeutic agents has been formally established via genetic studies, including the twin studies of Vessel and Page.[51–55] Barring formal genetic studies, the response distribution can also strongly suggest a heritable response. The inter-individual response distribution may be either multimodal or unimodal (Fig. 9-5). A multimodal distribution suggests distinct population subgroups of response, thereby directly supporting a pharmacogenetic basis for response. A unimodal drug response distribution still supports the concept of inter-individual variation, with subjects demonstrating both "good" and "poor" responses. The combination of wide inter-individual response with high repeatability (the likelihood of a subsequent beneficial/poor response to a drug given a prior response) supports the plausibility of a pharmacogenetic effect.[56]

Pharmacogenetics has traditionally been divided into four categories based upon the effects of genetic variability on the pharmacologic properties of a drug. For instance, one genetic variant can alter the

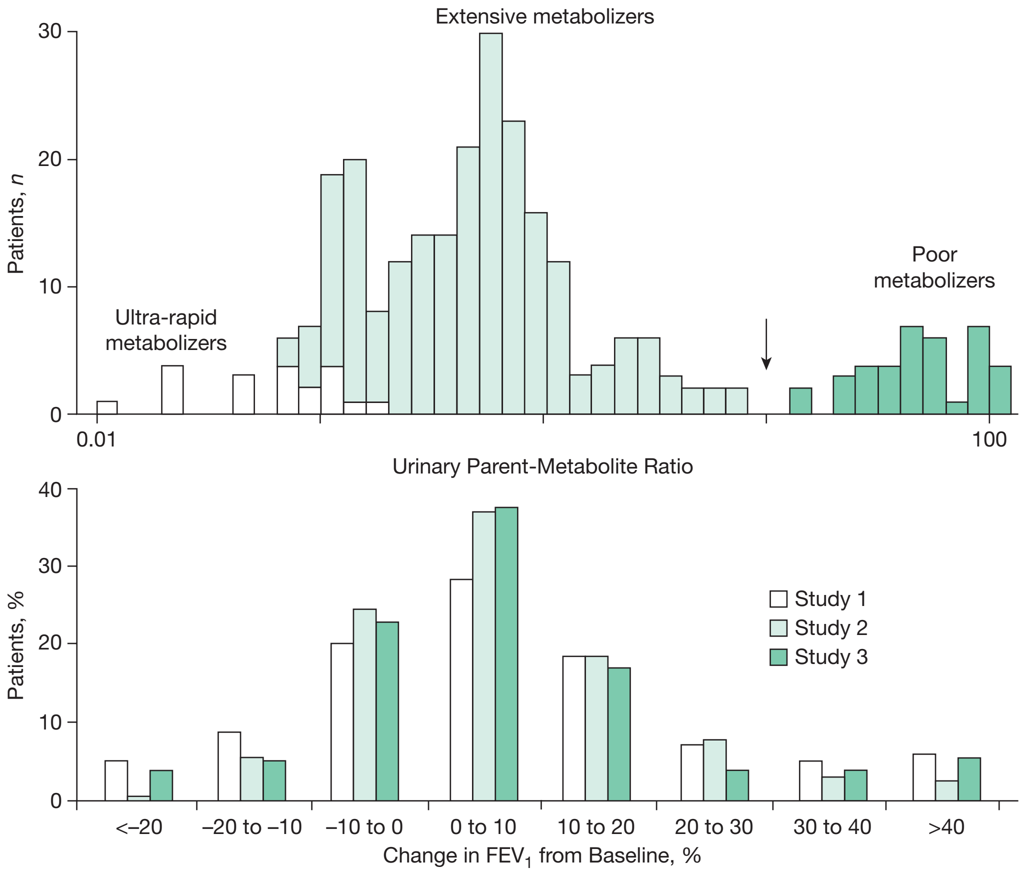

Figure 9-5 Patterns of variation in drug response. **Top.** multimodal response common to many drug metabolizing enzymes. **Bottom.** Unimodal, yet highly variable, response noted in complex trait drug response. In this case, studies 1–3 refer to three independent clinical trials that measured inhaled corticosteroid response over time. *(Reproduced with permission from Roden DM, Altman RB, Benowitz NL, et al. Pharmacogenomics: Challenges and Opportunities. Ann Intern Med. 2006;145(10):749–757.)*

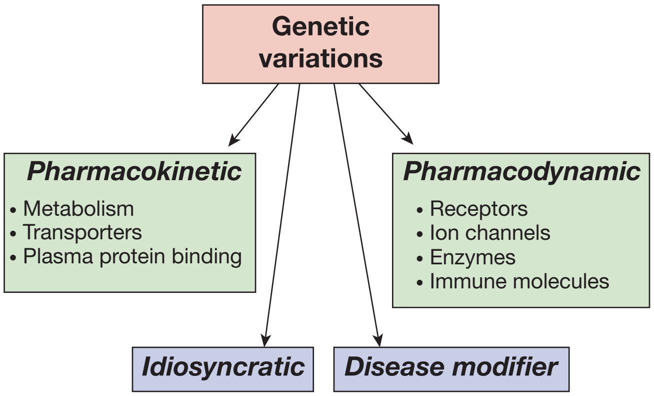

Figure 9-6 Categories of pharmacogenetic response, based upon site of activity of the genetic variant of interest.

rapidity of drug metabolism (thereby altering bioavailability), whereas another genetic variant can affect binding to a drug receptor (thereby decreasing therapeutic efficacy). The four categories include variation related to pharmacokinetics, pharmacodynamics, idiosyncratic reactions, and disease pathogenesis[57] (Fig. 9-6). Each of these categories will be discussed below, followed by a known example or examples pertinent to pulmonary medicine. Clinical implementation guidelines for several of these examples have been developed.[58–62] Additional examples likely to be encountered by the respiratory practitioner and labeled by the U.S. Food and Drug Administration (FDA) are listed in Table 9-7. *Pharmacokinetics* studies the effect of the body upon an administered drug, including the absorption, distribution, tissue localization, biotransformation, and excretion of drugs.[63] Common drug metabolizing enzymes implicated in pharmacogenetics and their estimated effect on drug dosing are shown in Fig. 9-7. The cytochrome p450 enzymes (*CYP*s) encode for ∼60%–70% of all phase I (i.e., structural transformation)-dependent metabolism and have been the classic examples of drug metabolizing enzymes. The clinically most important *CYP*s are *CYP2C9*, *CYP2D6*, and *CYP3A4*, with *CYP2C9* discussed in the context of warfarin administration below. *CYP* genotypes generally result in three metabolic phenotypes, ultra-rapid metabolizers, extensive (normal) metabolizers, and poor metabolizers (Fig. 9-5).

An example of polymorphic phase II (i.e., drug conjugation) drug metabolizing enzymes is the metabolism of azathioprine by thiopurine-*S*-methyltransferase (*TPMT*).[64] Azathioprine, which is commonly used in the therapy of interstitial lung disease and pulmonary vasculitides, is converted to the active 6-mercaptopurine, which is then metabolized by *TPMT* or converted into 6-thioguanine nucleotides. Decreased *TPMT* activity, as mediated through genetic variation, occurs in about 10% of individuals at intermediate levels, while ∼0.3% (1 in 300) have low to absent activity. Clinically, this results in drug-related myelosuppression in 5%, severe leukopenia in 1.2%, and mortality in 0.3% of subjects taking azathioprine.[65] Both clinical phenotyping (pre-drug assessment of *TPMT* activity) and genotyping assays are available. Such testing has been noted to be cost effective in a variety of diseases,[66–68] including modeling of azathioprine use in interstitial pulmonary fibrosis.[69] Clinical pharmacogenomic implementation guidelines have been published.[58,61]

Genetics can also influence drug transporters affecting drug absorption, distribution, and excretion. As an example, the solute carrier organic anion transporter family member 2B1 (*SLCO2B1*) mediates the Na(+)-independent transport of organic anions such as leukotriene C4. A nonsynonymous *SLCO2B1* polymorphism (rs12422149) has been associated with significantly reduced plasma concentration and differential response to therapy with montelukast as assessed by change in baseline Asthma Symptom Utility Index scores.[70]

Pharmacodynamics is the study of the biochemical and physiologic consequences of the administration of a drug and its mechanism of action,[63] i.e., the effect of a drug at its therapeutic target. Genetic variation may lead to response differences despite appropriate concentrations of a drug at its intended target. This category is especially pertinent to pulmonary medicine, since many conditions are treated with inhaled medications that bypass first-pass metabolism by the liver, thereby limiting the effect of pharmacokinetic variants.

Warfarin is the most commonly prescribed anticoagulant medication worldwide and in respiratory medicine is commonly used for the treatment of pulmonary embolism. For warfarin, cytochrome p450 2C9 (*CYP2C9*) is the primary enzyme involved in its metabolism, while vitamin K epoxide reductase complex, subunit 1 (*VKORC1*) is its primary therapeutic target, responsible for the conversion of vitamin K-epoxide to vitamin K. FDA labeling of warfarin includes consideration for testing of variants involved in both pharmacokinetics and pharmacodynamics. "High" and "low" dose risk variants of the *VKORC1* gene, as well as variants of the *CYP2C9* gene, have been identified.[71] Overall, *VKORC1* variants account for ∼25% of variability in warfarin dosing, with *CYP2C9* adding an additional 6% to 10%.

Multiple early studies supported the ability to predict initial warfarin dosing using a genotype-stratified approach.[71–75] Initial guidelines for the clinical implementation of warfarin pharmacogenetics have been detailed.[60,76] In two[77,78] of three initial published clinical trials comparing use of a pharmacogenetic algorithm to a clinical dosing strategy, no significant benefit was noted in terms of percentage of time spent within the therapeutic international normalized ratio (INR) range, with the third[79] demonstrating only a modest (67.4% to 60.3%) benefit to pharmacogenetics. While disappointing from a pharmacogenetic dosing standpoint, these studies were not powered to address the more important issue of bleeding and thrombotic complications. One study comparing a current genotyped cohort with historic controls demonstrated 31% fewer hospitalizations overall (adjusted hazard ratio [HR], 0.69; 95% CI, 0.58–0.82) and 28% fewer hospitalizations for bleeding or thromboembolism (HR, 0.72; 95% CI, 0.53–0.97) based upon pharmacogenetic dosing.[80] More recently, both the ENGAGE AF-TIMI 48 study and the GIFT study reported significant benefit in terms of time spent at therapeutic dosing and decreased risk of major bleeding events from pharmacogenetic testing for warfarin.[81,82] These outcomes are further supported by recent meta-analyses.[83,84]

Pharmacogenetic tests aimed at combining multiple genetic predictors will likely continue to be a focus going forward. For instance, variants in *CRHR1* and *GLCCI1* have been associated with lung function response to inhaled corticosteroids in multiple asthmatic populations.[85,86] However, these each account for just a small proportion of the variability in response to these medications. Nonetheless, combining two variants in the *CRHR1* and *GLCCI1* genes significantly improves the ability to predict response in a replicable fashion.[87]

The *idiosyncratic* category of pharmacogenetic response to drugs includes the individuals that experience an ADR to a therapeutic agent that could not be anticipated based upon the known drug target. Examples of the idiosyncratic category include some compounds that are metabolized by arylamine-*N*-acetyltransferase 2 (*NAT2*). Genetic differences in *NAT2* have been associated with predisposition to the development of peripheral neuropathy in certain individuals taking isoniazid[88] and hypersensitivity reactions to trimethoprim/sulfamethoxazole (including rash, granulocytopenia, and abnormal liver function tests).[88,89] Interestingly, the *NAT2* acetylator phenotype (based upon metabolized level of drugs) may correlate poorly with *NAT2* genotype,[90,91] suggesting that factors other than drug level may explain these idiosyncratic reactions associated with genetic variation.

TABLE 9-7 Common Pulmonary Medications FDA Labeled for Pharmacogenomic Effects

Drug	Therapeutic Area	Genotype(s)	Variant Genotype Effect	FDA-Labeled Sections
Afatinib	Oncology	*EGFR*	*EGFR* mutations are biomarker of afatinib efficacy in lung cancer	Indications and Usage, Dosage and Administration, Adverse Reactions, Clinical Studies
Arformoterol	Pulmonary	*CYP2D6, UGT1A1*	Direct glucuronidation of arformoterol is mediated by UGT1A1 and is the primary elimination route; O-demethylation is a secondary route catalyzed by CYP2D6 and CYP2C19	Clinical Pharmacology
Azathioprine	Interstitial lung disease	*TPMT, NUDT15*	Increased potential for bone marrow suppression	Dosage and Administration, Warnings, Precautions, Adverse Reactions, Clinical Pharmacology
Cisplatin	Oncology	*TPMT*	Children with variants may have an increased risk of ototoxicity	Adverse Reactions
Codeine	Analgesics, cough suppression	*CYP2D6*	Decreased pain relief in poor metabolizers	Boxed Warning, Warnings and Precautions, Use in Specific Populations, Patient Counseling Information
Dapsone	Anti-infective	*G6PD*	Hemolytic anemia	Precautions, Adverse Reactions, Overdosage
Erlotinib	Oncology	*EGFR*	EGFR-TK mutation is biomarker of erlotinib efficacy in lung cancer	Indications and Usage, Dosage and Administration, Adverse Reactions, Clinical Studies
Formoterol	Pulmonary	*CYP2D6, CYP2C19*	Metabolized by O-demethylation, which is catalyzed by CYP2D6 and CYP2C19	Clinical Pharmacology
Gefitinib	Oncology	*EGFR, CYP2D6*	EGFR-TK mutation is biomarker of gefitinib efficacy in lung cancer; reduced function of CYP2D6 leads to gefitinib-induced rash and has been associated with hepatotoxicity when CYP3A4 also is inhibited	Indications and Usage, Dosage and Administration, Clinical Studies
Imatinib	Pulmonary hypertension	*KIT*	cKIT mutations may exhibit decreased efficacy	Indications and Usage, Dosage and Administration, Clinical Studies
Indacaterol	Pulmonary	*UGT1A1*	UGT1A1 metabolizes indacaterol to the phenolic O-glucuronide	Clinical Pharmacology
Irinotecan	Oncology	*UGT1A1*	Increased potential for severe diarrhea and fatal neutropenia	Dosage and Administration, Warnings and Precautions, Clinical Pharmacology
Isoniazid	Anti-infective	*NAT1; NAT2*	Increased risk of peripheral neuropathy with *NAT1* variation; attenuated with pyridoxine administration; *NAT2* influences drug level	Clinical Pharmacology
Ivacaftor	Pulmonary	*CFTR (G551D)*	G551D genotype is one benefitting from actions of ivacaftor	Indications and Usage, Adverse Reactions, Use in Specific Populations, Clinical Pharmacology, Clinical Studies
Lansoprazole	Gastroenterology	*CYP2C19*	Increased efficacy (higher intragastric pH) vs. extensive (normal) metabolizers	Drug Interactions, Clinical Pharmacology
Mercaptopurine	Oncology	*TPMT, NUDT15*	Increased potential for bone marrow suppression	Dosage and Administration, Warnings and Precautions, Adverse Reactions, Clinical Pharmacology
Mycophenolic acid	Transplantation	*HPRT1*	Should be avoided in patients with hereditary deficiency of hypoxanthine-guanine phosphoribosyl-transferase (*HPRT1*) such as Lesch-Nyhan and Kelley-Seegmiller syndromes.	Warnings and Precautions
Omeprazole	Gastroenterology	*CYP2C19*	Increased efficacy (higher intragastric pH) vs. extensive (normal) metabolizers	Drug Interactions, Clinical Pharmacology
Umeclidinium	Pulmonary	*CYP2D6*	Umeclidinium is metabolized by CYP2D6	Clinical Pharmacology
Voriconazole	Antifungals	*CYP2C19*	Possible risk of subtherapeutic voriconazole concentrations, and subsequently of treatment failure	Clinical Pharmacology
Warfarin	Hematology	*CYP2C9; VKORC1*	Higher warfarin levels and increased potential for adverse effects	Dosage and Administration, Drug Interactions, Clinical Pharmacology

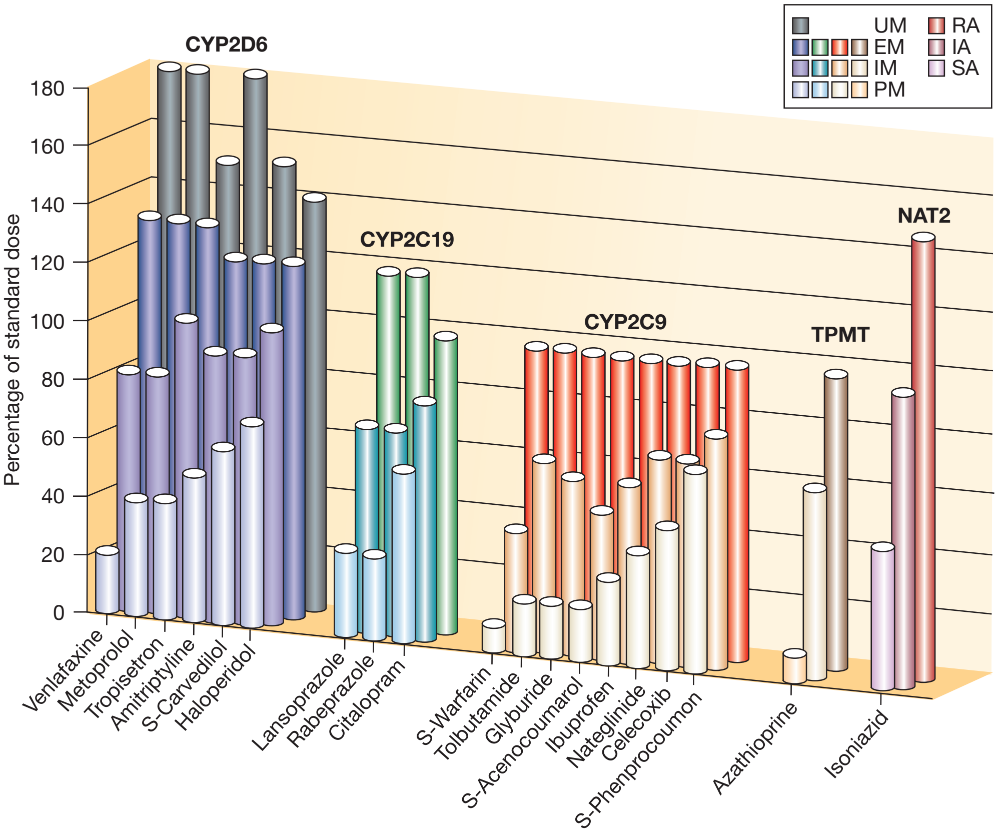

Figure 9-7 Common drug metabolizing enzymes and their standardized effect on drug dosing, according to the difference in pharmacokinetic parameters from clinical studies. Substantial adjustments need to be made to drug dose to achieve the same level of drug exposure in individuals with different genotypes. EM, extensive metabolizer; IA, intermediate acetylator; IM, intermediate metabolizer; PM, poor metabolizer; RA, rapid acetylator; SA; slow acetylator; UM, ultra-rapid metabolizer. *(Reproduced with permission from Kirchheiner J, Fuhr U, Brockmoller J. Pharmacogenetics-Based Therapeutic Recommendations Ready for Clinical Practice? Nat Rev Drug Discov. 2005;4(8):639–647.)*

The final pharmacogenetic category is that of genetic factors influencing *disease pathogenesis.* By modifying the underlying biology/severity of the disease, these genetic factors can also influence which therapies will work or how effective a given medication might be. As a brief example, in cystic fibrosis, the *CFTR*ΔF508 variant has been associated with earlier colonization with *Pseudomonas aeruginosa*,[92] whereas the G551D mutation has a milder clinical phenotype with later *P. aeruginosa* colonization.[93] Therefore, *CFTR* genotype would affect both severity of disease and frequency of antibiotic dosing.

In addition to pharmacogenetics, which focuses on DNA variants, pharmacogenomic drug response studies have begun to focus on the influence of other genomic data types. As an example, our group recently noted that, following small RNA sequencing in a large asthma cohort, two microRNAs with the ability to modify glucocorticoid-mediated transrepression of NfκB (the primary immunosuppressive mechanism for corticosteroid medications), miR-155-5p and miR-532-5p, were able to predict long-term lung function response to inhaled corticosteroids (AUROC, 0.86). The rapidly increasing availability of large-scale “omic” technologies that permit large scale profiling of the transcriptome, epigenome, proteome, metabolome, and microbiome at unprecedented levels of detail, such as single-cell RNA sequencing, will serve to dramatically increase the number of precision pulmonary studies in the near future.

PERSONALIZED PULMONARY MEDICINE: THE CHALLENGE

Though the use of genetics in clinical practice is gradually being adopted for the evaluation of rare lung diseases, the same is not true for more common lung disease. Despite the availability of personalized diagnostic panels, labeling changes implemented by regulatory agencies (e.g., the FDA), and an ever-increasing compilation of genetic, biomarker, and pharmacogenetic studies in the literature, actual translation of personalized pulmonary testing for common lung diseases from the bench to the bedside has been slower than expected, and the existing available tests may still be suboptimal. There are several of reasons for this delay. In the preceding sections, we have outlined how low heritability, variable penetrance, and the need for large effect sizes may affect test performance. Other implementation issues include (1) limitations in the design of published studies, (2) regulatory and ethical concerns, (3) lack of cost effectiveness analyses, and (4) need to educate both patients and providers.

■ Study Design Limitations

Despite the availability of numerous reported genetic and pharmacogenetic associations in the literature, many have not been reproduced in subsequent studies.[94,95] False-positive initial associations may be due to the fact that many pharmacogenetic studies are “spin-offs” from clinical trials or for improperly designed case-control studies and, thus, are underpowered for genetic association. The nature of clinical trials (for pharmacogenetics) and of individualized cohorts (for genetic association) may also result in multiple distinct clinical phenotypes, which vary from study to study. This “phenotypic heterogeneity” combined with “genotypic heterogeneity” (interrogating disparate markers within the same gene) may also contribute to failure to replicate initial findings. These issues were detailed in an evaluation of the pharmacogenetic associations of the β2-adrenergic receptor (*ADRB2*) gene[96] with β_2-agonist response in asthma.

Overall, in 21 studies that focused on the two most common *ADRB2* coding variants (Arg16Gly and Gln27Glu), there were large differences in study design for both genotype definition (e.g., single variant vs. haplotype) and phenotypic outcome. Of a total of 487 interrogated associations, only two associations were probed in at least five of the studies, for the same endpoint, time of assessment, type of intervention, and genetic group. Not surprisingly, no definitive conclusions have been made regarding the utility of *ADRB2* variants to guide asthma therapy. Clearly, a continued focus on appropriate phenotypes and more precise replication of existing data are needed.

While beyond the scope of this chapter, two additional topics related to study design should be mentioned. The first relates to systems biology and personalized medicine. Given that multiple genetic and environmental factors impact the majority of respiratory disease susceptibility and treatment response, systems approaches seek to integrate data both at the level of data type (e.g., epistasis or gene-gene interactions) and across data types (e.g., integration of biomarker, gene expression, and SNP data) to formulate predictive models.[97–101] While young, this approach is promising with regard to complex trait test development. The second additional point is the ongoing controversy regarding study design and whether prospective, genotype-stratified trials are necessary prior to implementation of pharmacogenetic testing. One perspective is that dosing and administration of drug changes warrant such trials, while the other perspective argues that genotypes are invariant (since people are born with them) and therefore precede even retrospective studies. A potential compromise might be in the use of adaptive clinical trials, with pharmacogenomics and other biomarkers included as part of the main trial adaptations.[102,103]

■ Regulatory and Ethical Concerns

As noted above, the FDA has been proactive in terms of pharmacogenetics, with pharmacogenetic information included on about 10% of labels for drugs approved by the FDA. Nevertheless, questions regarding the regulation of genotyping tests and the extent to which pharmacogenetic analyses should be incorporated into new drug development before or after large clinical trials, remain.[104] While beyond our current scope, one detailed perspective on how pharmacogenetic testing might be included in each phase of clinical drug development has been recently published.[105] Another potential boon to genetic test development is the recent ruling by the U.S. Supreme Court that genes cannot be patented.[106,107]

From an ethics perspective, the long-standing concern has been whether genetic variants could result in stigmatization (e.g., denied insurance).[104] A major step in the protection of individuals' rights came with the passage of H.R. 493, the Genetic Information Nondiscrimination Act of 2008. This law protects Americans against discrimination based on their genetic information in matters related to health insurance and employment and should translate into increased acceptance of personalized testing by the public in the future.

■ Lack of Cost-Effectiveness Analyses

Despite the multitude of pharmacogenetic association studies in the literature, relatively few cost-effective analyses have been performed. These studies will be crucial prior to the availability of widespread reimbursement for routine personalized pulmonary testing. Circumstances that favor cost effectiveness of a genetic test include the following: a high prevalence of the genetic variant of interest in the target population, good correlation between phenotype and genotype, satisfactory diagnostic test criteria, disease associated with significant morbidity or mortality if left untreated or undiagnosed, and, for pharmacogenetic variants, significant reduction in adverse drug reactions resulting from testing.[108]

■ Need to Educate Both Patients and Providers

Pharmacogenetics and the promise of personalized medicine have been frequently mentioned in the popular lay press. It is therefore incumbent upon both the developers of a given test, as well as health care professionals responsible for ordering the test, to be cognizant of the test characteristics and interpretation and to be able to effectively disseminate that information to patients. In turn, in the era of personalized medicine, the need for educating health care providers in both the broad array of potential predictive tools (in addition to genetic variants, genomic, proteomic, and other molecular biomarkers will be increasingly available), as well as the strengths and weakness of each of these approaches, will be needed. The context for these educational efforts is not yet clear. Given available tests, providers will potentially need a diagnostic step to determine which drug is best suited to each patient. Of paramount importance, providers will need to be reassured and cognizant that these tests will not and cannot replace sound clinical judgment.

CONCLUSION

Variation in the susceptibility to disease and response to drugs within pulmonary medicine has a significant heritable component. Although many challenges remain, testing of personalized pulmonary medicine, biomarkers, and pharmacogenetics has begun in earnest. Given the rapidity of new genetic, genomic, and other biomarker knowledge, we are making progress toward the goal of individualized medicine.

SECTION 2 Physiological Principles of Normal Lung Function

CHAPTER 10

Pulmonary Mechanics*

Allan I. Pack
Michael A. Grippi

OVERVIEW

"Arterialization" of venous blood requires matching of the distribution of air and blood within the lung, thereby ensuring effective gas exchange across the alveolar–capillary membrane. Arterialization comprises a series of interrelated processes that begin with the mechanical performance of the ventilatory apparatus—that is, the lungs and the chest wall, including the rib cage, diaphragm, and abdominal wall. Ventilation is critical for replenishing fresh air to the lungs for gas exchange. Although the function of each component of the lung and of the chest bellows can be deranged by injury or disease, the design of the ventilatory apparatus provides for considerable reserve. As a result, mechanical derangements are usually quite severe by the time clinical symptoms appear or arterial blood-gas levels become abnormal.

In many clinical instances, characterization of the mechanical abnormality provides insight into disease pathogenesis and affords a quantitative measure of severity. This is true in a variety of settings, including management of ventilator-dependent patients in the intensive care unit.[1]

During breathing, the lungs and chest wall operate in unison. The lungs fill the chest cavity so that the visceral pleurae are in contact with the parietal pleurae of the chest wall. The two pleural surfaces are separated by only a thin liquid film, which interconnects the lungs and chest wall.

At the end of a normal exhalation, when the respiratory muscles are at rest, the ventilatory apparatus is in a state of mechanical equilibrium. The pressure along the entire tracheobronchial tree from the airway opening to the alveoli is equal to atmospheric pressure ("zero gauge pressure"). The tendency of the lung is to deflate, however, and lung elastic recoil is directed inwardly toward the center of the chest cavity (i.e., centripetally). This is counterbalanced by the elastic recoil of the chest wall, which is directed outwardly (i.e., centrifugally) to favor an increase in volume. These opposing forces generate a subatmospheric pleural pressure of about -5 cmH$_2$O (Fig. 10-1A). The tendency for the lung to recoil inward and for the chest wall to recoil outward is illustrated by the observation that when the chest is opened at autopsy, the lungs collapse to a nearly airless state, and the thorax expands.

Although conventionally pleural pressure is considered a single, mean value that reflects mechanical events within the entire ventilatory apparatus, this is clearly an oversimplification on several accounts: (1) pleural pressure is not directly determinable because normally there is only a potential space between the visceral and parietal pleura; (2) on conceptual grounds, distinctions exist between surface and liquid pleural pressures; (3) pleural pressures are not uniform over the surface of the lungs, since they are strongly affected by gravity; and (4) transmission of pleural pressures at the surface to alveoli located at different depths and loci with the lungs depends on the structural interplay among supporting structures in the alveolar walls ("interdependence"), which resists any inclination of individual alveoli or even a lobule to collapse.[2] Nonetheless, the concept of *mean pleural pressure*, as generally used in considerations of respiratory system mechanics, has proved to be of great practical value.[3]

Contraction of the muscles of inspiration produces the forces that permit the flow of gas along the tracheobronchial tree and lung and chest wall expansion. The movement of air into the lungs requires a pressure difference between the airway opening and the alveoli sufficient to overcome the resistance to airflow of the tracheobronchial tree. Additionally, a pressure difference across the alveolar walls (i.e., between the alveoli and pleural space) must be generated to overcome elastic recoil and inflate the lungs. During spontaneous breathing, the action of the inspiratory muscles causes an increased outward pull on the chest wall.[4] As a result, the pleural pressure becomes more subatmospheric. This pressure change is transmitted to the interior of the lungs, so alveolar pressure also becomes subatmospheric (Fig. 10-1B). In contrast, during artificial ventilation with a positive-pressure ventilator, a supra-atmospheric pressure applied at the inlet to the airways creates a pressure gradient between the airway opening and alveoli to create airflow.

Expansion of alveoli depends on the achievement of an adequate distending pressure across alveolar walls. This distending pressure, or *transpulmonary pressure*, is the difference between alveolar (P_A) and pleural (P_{pl}) pressures. As shown in Fig. 10-1A, the transpulmonary pressure at end expiration ($P_A - P_{pl}$) is 5 cmH$_2$O. At end-inspiration (Fig. 10-1C), the lungs contain more air, and the distending pressure, which also represents the recoil pressure, is greater.

The energy used during inspiration to overcome the elastic resistance of the lungs is stored. Expiration occurs when these forces are released. When the inspiratory muscles relax, the recoil of the lungs causes the alveolar pressure to exceed the pressure at the mouth, and air flows out of the lungs. Although expiration during quiet breathing is passive, with high ventilatory requirements (e.g., during exercise), the expiratory muscles engage to assist movement of air out of the lungs.

LUNG VOLUMES

The lung volumes and capacities (Table 10-1) are also considered elsewhere in this book (see Chapter 31). The end-expiratory position of the lungs, known as *functional residual capacity* (FRC), is the major reference point for the subdivisions of lung volume. This position is set by the opposing recoil forces of the lungs and chest wall when the respiratory muscles are at rest.

Total lung capacity (TLC), which is the total volume of air contained in the lungs after a maximal inhalation, is determined by the balance between the force-generating capacity of the inspiratory muscles and the opposing elastic recoil forces of the lungs and chest wall.[5] Weakness of the muscles of inspiration or increased stiffness of the lungs reduces TLC. Loss of retractive forces exerted by the lung, as seen in emphysema, increases TLC.

Residual volume (RV), defined as the volume of air remaining in the lungs after a complete exhalation, is set by the balance between the actions of the expiratory muscle and the recoil forces of the lungs, which act to decrease lung volume, and the outward recoil

forces of the chest wall, which favor lung expansion. In middle-aged and older individuals, closure of airways at low lung volumes and resulting air trapping is an important determinant of RV.[6]

STATIC MECHANICAL PROPERTIES OF THE RESPIRATORY SYSTEM

Assessment of the elastic properties of the respiratory system is best assessed by evaluating the elastic properties of the lungs and chest wall separately. Elastic properties are conventionally determined over a fixed range of volumes during periods of no airflow.

■ Elastic Properties of the Lungs

The change in transpulmonary pressure required to effect a given change in the volume of air in the lungs is a measure of the distensibility, or *compliance*, of the lungs. Pulmonary compliance is calculated as the ratio of the change in lung volume to the change in transpulmonary pressure:

$$C = \frac{\Delta V_L}{\Delta(P_A - P_{pl})}$$

where

C = lung compliance
$\Delta(P_A - P_{pl})$ = change in transpulmonary pressure
P_A = alveolar pressure and P_{pl} = pleural pressure
ΔV_L = change in lung volume

TABLE 10-1 Lung Volumes and Subdivisions

The *functional residual capacity* (FRC) is the volume of air that remains in the lungs at the end of a normal expiration.
The *tidal volume* (TV) is the volume of air that is drawn into the lungs during inspiration from the end-expiratory position (and also leaves the lungs passively during expiration) in the course of quiet breathing.
The *expiratory reserve volume* (ERV) is the maximum volume of air that can be forcibly exhaled after a quiet expiration has been completed (i.e., from the end-expiratory position).
The *residual volume* (RV) is the volume of air that remains in the lungs after a maximal expiratory effort.
The inspiratory capacity (IC) is the maximum volume of air that can be inhaled from the end-expiratory position. It consists of two subdivisions: tidal volume and the *inspiratory reserve volume* (IRV).
The *total lung capacity* (TLC) is the total volume of air contained in the lungs at the end of a maximum inspiration.
The *vital capacity* (VC) is the volume of air that is exhaled by a maximum expiration after a maximum inspiration.

Compliance denotes distensibility, i.e., the ease of stretch or inflation. The inverse of compliance is known as *elastance* and refers to the stiffness or the tendency to resist distortion and to return to the original configuration when the distorting force is removed.

In practice, pulmonary compliance is determined by relating the changes in transpulmonary pressure to the changes in lung volume during interruptions in airflow in the course of an expiration following a maximal inspiration (i.e., starting from TLC).

The pressure–volume characteristics of the lung are nonlinear. As lung volume increases, the elastic elements approach their limits of distensibility, and a given change in transpulmonary pressure produces progressively smaller increases in lung volume.[7,8] Thus, the compliance of the lung is least at high lung volumes and greatest as RV is approached (Fig. 10-2). Elastic recoil forces favoring collapse of the lung can be demonstrated throughout the range of the vital capacity, even at low lung volumes approaching RV. If the opposing forces of the chest wall on the lungs are eliminated—for instance, by removing the lungs from the thorax or by opening the chest—the

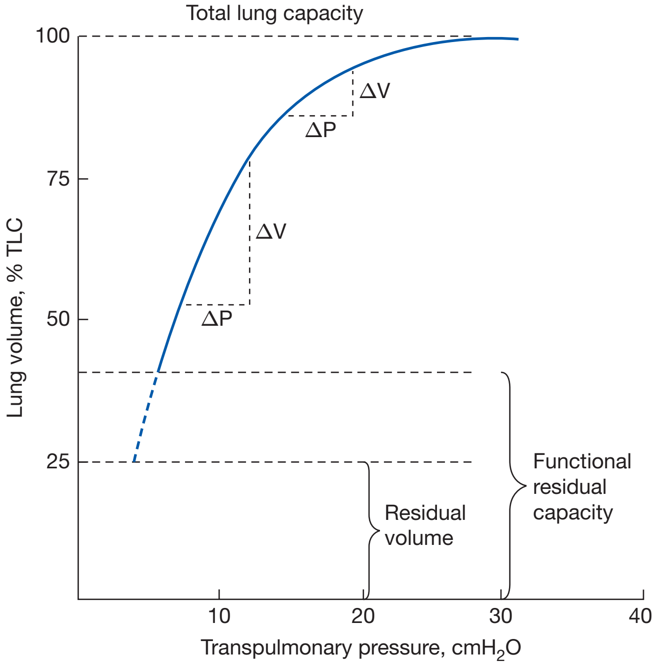

Figure 10-2 Pressure–volume curve of the lung. The static elastic recoil pressure of the lung is approximately 5 cmH_2O at FRC and 30 cmH_2O at TLC. The compliance of the lung (ΔV/ΔP) is greater at low lung volumes than at high lung volumes.

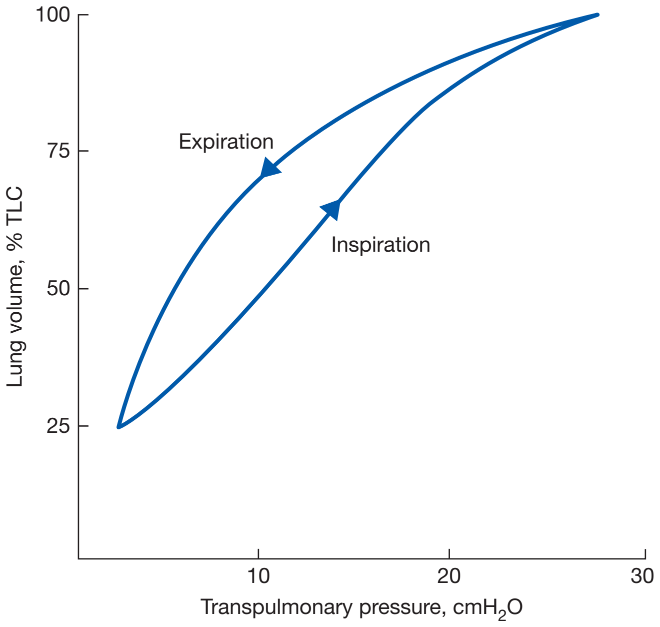

Figure 10-3 Pressure–volume curves of the lung during inspiration and expiration.

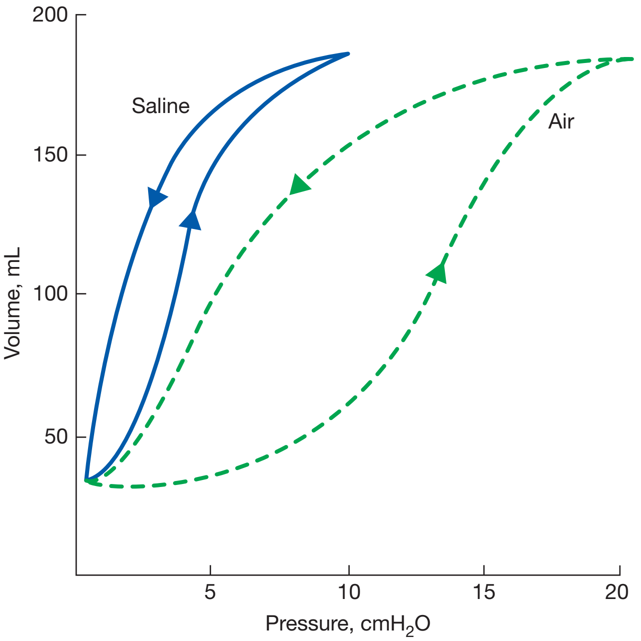

Figure 10-4 Comparison of pressure–volume relationships of air- and saline-filled excised lungs. *Arrows* directed upward indicate inflation; those directed downward indicate deflation. Since saline eliminates surface forces at the liquid–air interface without affecting tissue elasticity, the difference in pressure between the two curves, at any lung volume, is that required to overcome surface forces. To maintain a small lung volume, a large proportion of the pressure is used to overcome surface forces. In contrast, at high lung volumes a greater fraction of the pressure is used to overcome tissue elasticity.

lung collapses to a near-airless state. A minimal volume of air does remain in the lungs because of closure of small airways resulting in the trapping of air in more distal airspaces.

If static measurements of transpulmonary pressure are made during lung inflation, rather than deflation, the pressure–volume curve has a different configuration (Fig. 10-3). This indicates that the elastic recoil of the lung depends not only on the lung volume at which the determination is made, but also on the "volume history" of the lung,[9] known as *hysteresis*, as described below.

Hysteresis

Differences in the pathways of the static pressure–volume curve during inspiration (when force is applied) and expiration (when force is withdrawn) are designated as hysteresis, which is a property of all elastic structures. In the lungs, it is due to the surface forces and the properties of the surface material lining the alveolar walls, as well as the elastic properties of the tissues. The tissues of the lungs are also subject to stress adaptation whereby, over time, the pressure required to maintain a given lung volume declines.[10] An additional factor relates to the closure of small airways at low lung volumes. Once these airways close, the lung units that they serve will not expand during inspiration until a critical opening pressure has been exceeded; only then will the closed units inflate. Recruitment of additional lung units as increasing transpulmonary pressure expands the lungs from low lung volume contributes to the hysteresis of the pressure–volume curve.

The elastic behavior of the lung depends on two factors: the physical properties of the lung tissue, per se, and the surface tension of the film lining the alveolar walls.

Surface Forces

The interior surfaces of the alveoli are lined by a thin liquid layer of osmophilic material. The surface tension at the air–liquid interface of the alveoli, in addition to the elastic properties of the parenchyma, contributes importantly to the elastic recoil of the lungs and acts to decrease lung compliance.[11] The cohesive forces between the molecules of the liquid lining of the alveoli are stronger than those between the film and alveolar gas, thereby causing the film to shrink to its smallest surface area. The behavior of this surface film has been examined in experimental animals by comparison of pressure–volume relationships of air-filled lungs with those of saline-filled lungs; saline eliminates the liquid–air interface without affecting elastic properties of the tissue. A lung distended with saline requires a lower transpulmonary pressure to maintain a given lung volume than a lung that is inflated with air.[12] Also, hysteresis is less in the saline-filled lung. The greater hysteresis in the air-filled lung is explained by the surface tension of the film lining the alveoli, which is higher during inflation as the film expands than it is during deflation as the film is compressed (Fig. 10-4).

By considering the alveolus to be a sphere, Laplace's law can be applied. Laplace's law states that the pressure inside a spherical structure—for example, the alveolus—is directly proportional to the tension in the wall and inversely proportional to the radius of curvature:

$$\text{Alveolar pressure} = \frac{2T}{r}$$

where

T = tension (dyn/cm)
r = radius

Abolition of the liquid–air interface by the instillation of saline into the alveolar spaces eliminates surface forces, thereby reducing the transpulmonary pressure required to maintain a given lung volume.

The surface film lining the alveoli of the lung is termed *surfactant*.[13] The superficial layer of the film facing the alveolar air is made up of surface-active phospholipids, notably dipalmitoyl lecithin. The deeper layer, termed the hypophase, consists of surface-active phospholipids linked to protein. Surfactant is generated by type II alveolar cells and undergoes a continuous cycle of formation, removal, and replenishment.[14]

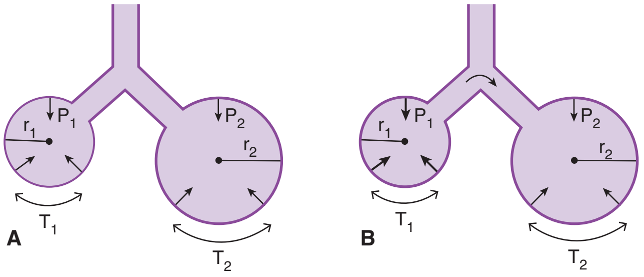

Figure 10-5 The effects of surfactant in maintaining alveolar stability. **A.** Surfactant lowers the tension of the alveolar walls at low lung volumes. Consequently, the transpulmonary pressure (P) of large and small communicating airspaces is the same. $r_1 < r_2$, $T_1 < T_2$, $P_1 = P_2$. **B.** Without surfactant, the surface tension remains constant as lung volume changes, and the recoil pressure of small airspaces exceeds that of larger ones. As a result, small alveoli tend to empty into larger ones. $r_1 < r_2$, $T_1 = T_2$, $P_1 > P_2$.

Surfactant serves several important functions. The surface tension of surfactant is inherently low and decreases even further at low lung volumes when the surface area of the film is reduced. The minimization of surface forces, particularly at low lung volumes, minimizes the adherence of the walls of distal airways that tend to close at low lung volumes and increases the compliance of the lung and decreases the work required to inflate the lungs during the next breath. The automatic adjustment of surface tension as lung volume changes also promotes stability of alveoli at low lung volumes; if the surface tension were to remain constant instead of changing with lung volume, the transpulmonary pressure required to keep an alveolus open would increase as the radius of curvature diminished with decreasing lung volume. Therefore, small alveoli would empty into the larger ones with which they communicate, and atelectasis would be a regular occurrence (Fig. 10-5). Surfactant dysfunction, as occurs with acute lung injury, i.e., acute respiratory distress syndrome (ARDS), results in marked increases in surface tension causing stiffening and instability of alveoli and leads to alveolar collapse (see Chapters 140 and 141).

Interdependence and Collateral Ventilation

The low surface tension of surfactant is not the most important determinant of alveolar stability. In reality, the alveoli form a froth rather than individual bubbles.[15] The walls of each alveolus are shared in common with those of adjacent alveoli so that contiguous airspaces attached by their connective tissue framework are tethered to one another and are not free to move independently. The tendency of any one alveolus to collapse is opposed by the traction exerted by the surrounding alveoli. This mechanical interdependence of adjacent airspaces resists the collapse of individual alveoli and serves as a stabilizing influence and ensures uniform inflation.[16] Even when a distal airway is completely obstructed, the alveoli served by the airway can still be ventilated through collateral channels between alveoli (*pores of Kohn*) and from bronchioles to alveoli (*canals of Lambert*). This collateral ventilation also prevents alveolar collapse and enhances the uniformity of ventilation, particularly in patients with lung disease.[17]

Physical Properties of Lung Tissue

A variety of tissue components contribute to lung elasticity. The pleura, the intralobular septa, peripheral airway smooth muscle tone, and pulmonary vasomotor tone, as well as the tissues of the alveolar walls, play a role in shaping lung elastic recoil.

The major connective-tissue elements of the alveolar walls are the collagen and elastin fibers.[18] Elastin fibers in the alveolar walls and surrounding the bronchioles and pulmonary capillaries have a low tensile strength but can be stretched to over twice their resting length. Elastin fibers are thought to bear most of the stress in the lung at low volumes. Collagen fibers have high tensile strength but are poorly extensible and probably act to limit expansion at high lung volumes.[19] Like a stretched nylon stocking, expansion of the lungs appears to entail an unfolding and geometric rearrangement of the fibers and only slight elongation of individual fibers.

As a result of alterations in the elastin and collagen fibers in the lung, the distensibility of the lungs (measured as compliance) increases with age.[8] This is part of the normal aging process. Pulmonary compliance is also increased by the destruction of alveolar walls and the enlargement of alveolar spaces that characterize pulmonary emphysema. In contrast, the distensibility of the lungs is reduced by pulmonary fibrosis, which stiffens its interstitial tissues.[7]

■ Elastic Properties of the Thorax

The elastic recoil of the chest wall is such that if it were unopposed by the lungs, the chest would enlarge to approximately 70% of TLC. This position represents its equilibrium or resting position.[20] In this position (when the respiratory muscles are completely relaxed), the pressure difference across the chest wall—that is, the difference between pleural pressure and the pressure at the surface of the chest—is zero. If the chest were forced to enlarge beyond its equilibrium position by an increasingly positive pleural pressure or by the application of subatmospheric pressure at the body surface, it would, like the lung, recoil inward, resisting expansion and favoring return to its equilibrium position. Conversely, at volumes less than 70% of TLC, the recoil of the chest is opposite that of the lung and is directed outward (Fig. 10-6).[21]

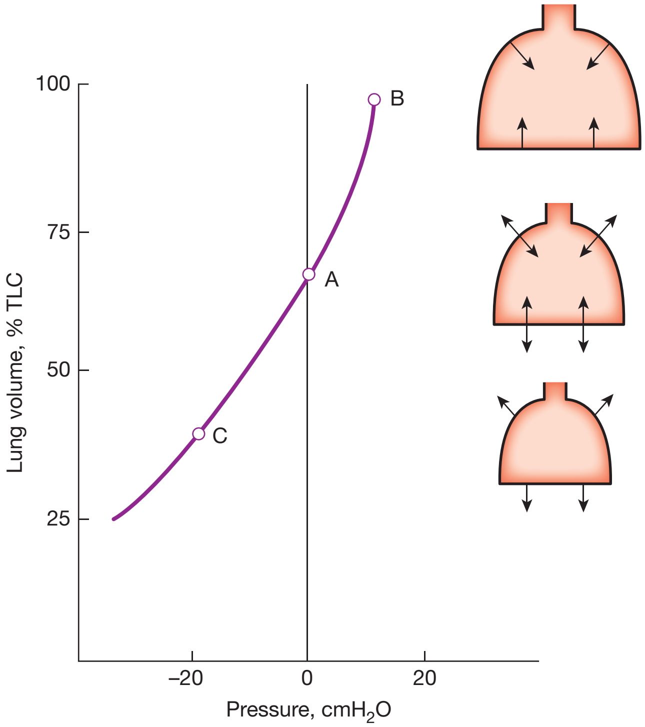

Figure 10-6 Pressure–volume relationships of the isolated chest wall. The direction of the recoil forces across the chest wall is represented by the *arrows*. The equilibrium position of the chest wall at point A, unopposed by the lungs, is approximately 70% of the total lung capacity. In this position, the pressure difference across the chest wall is zero. At larger volumes (B), there is inward recoil of the chest wall; at volumes below the equilibrium position (C), the recoil of the chest wall is directed outward, favoring expansion.

The chest wall can also be represented as a two-compartment system consisting of the rib cage and the abdomen, and volume changes can be partitioned between the two compartments.[22] Changing from the upright to the supine position at a constant overall lung volume produces a shift in volume from the abdominal to the rib cage compartment. The compliance of the rib cage is similar in the supine and upright positions, but the compliance of the abdominal compartment—particularly at high volumes—is greater in the supine position.[23]

The elastic recoil properties of the chest wall play an important role in determining the subdivisions of lung volume. They may be seriously deranged by disorders affecting the chest wall, such as marked obesity,[24] kyphoscoliosis, and ankylosing spondylitis.

■ Elastic Properties of the Respiratory System as a Whole

During breathing, the lung and the chest wall move together and operate mechanically in series. At any given lung volume, the elastic recoil pressure of the total respiratory system (P_{rs}) can be calculated as the algebraic sum of the pressures exerted by the elastic recoil of the lung (transpulmonary pressure) and the elastic recoil of the chest wall.[25]

Since the elastic recoil of the lung is determined (under static conditions of arrested airflow) as the difference between alveolar pressure (P_A) and pleural pressure (P_{pl})—that is, $P_A - P_{pl}$—and the elastic recoil of the chest wall is determined (while the respiratory muscles are completely at rest) as the difference between pleural pressure and the pressure at the external surface of the chest (P_{bs})—that is, $P_{pl} - P_{bs}$, the elastic recoil of the entire respiratory system can be expressed as the sum of the two:

$$P_{rs} = (P_A - P_{pl}) + (P_{pl} - P_{bs}) = P_A - P_{bs}$$

Thus, a measure of the elastic recoil of the respiratory system is supplied by the alveolar pressure, provided that the respiratory muscles are completely at rest and the pressure of the body surface is at atmospheric levels. In the absence of airflow into or out of the lung and when the glottis is open, alveolar pressure corresponds to the pressure at the mouth.

Relaxation Pressure–Volume Curve

The elastic properties of the entire respiratory system can be determined from the relaxation pressure–volume curve (Fig. 10-7). FRC represents the equilibrium position of the lung–chest wall system while the respiratory muscles are relaxed. At this point, the opposing recoils of the lung and chest wall are of equal magnitude, and the recoil pressure of the entire respiratory system is zero. With increases in lung volume above FRC, the recoil pressure of the entire system becomes positive, owing to the combination of an increase in centripetal elastic recoil of the lungs and a decrease in the centrifugal recoil of the chest wall. The net effect favors a decrease in lung volume, and lung volume can be maintained with the airway open to the atmosphere only by the action of the inspiratory muscles. As lung volume exceeds 75% of TLC, the recoil of the chest wall also becomes centripetal, and the recoil pressure of the chest wall adds to the inward forces acting to diminish lung volume. TLC represents the lung volume at which the inward passive elastic recoil pressure of the respiratory system reaches the maximum force that can be generated by the inspiratory muscles.

At lung volumes below FRC, when the centrifugal recoil of the chest wall exceeds the reduced centripetal recoil of the lungs, the relaxation pressure is negative, and this net effect favors an increase in lung volume. Lung volumes below FRC are achieved and maintained by the muscles of expiration.

A switch from the sitting to the supine position decreases FRC because of the effects of gravity. In the upright position, gravity pulls the abdominal contents away from the chest wall. In contrast, in the supine position, the push of the abdominal contents against the diaphragm decreases the centrifugal recoil of the chest wall. The chest wall pressure–volume curve—and, consequently, the pressure–volume curve of the entire respiratory system—is displaced to the right.

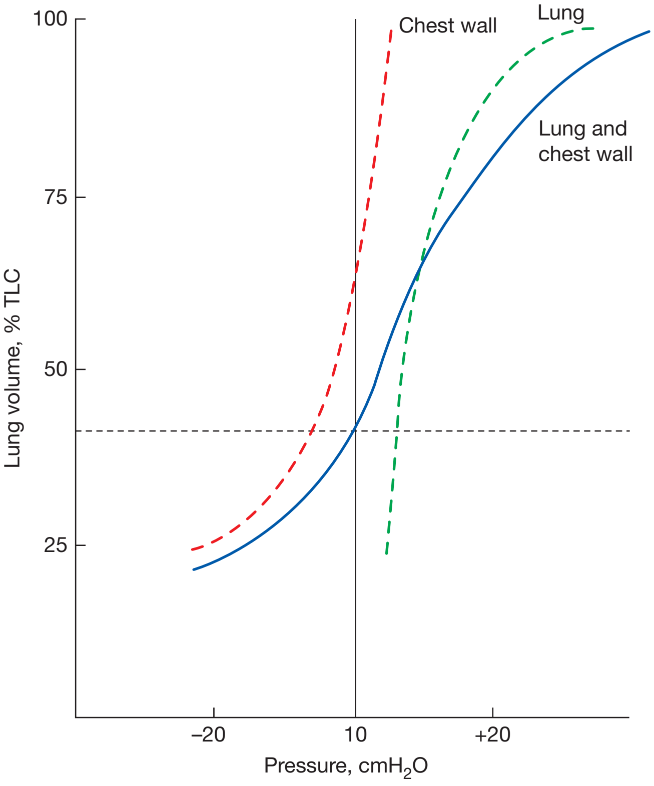

Figure 10-7 Relaxation pressure–volume curves. The lungs and the chest wall function mechanically in series so that the elastic recoil pressures of the total respiratory system, represented by the *solid line*, is the algebraic sum of the separate recoil pressures of the lung and chest wall. At the volume represented by the horizontal *dashed line*, the recoil pressures of the lung and chest wall are equal but in opposite directions. Consequently, the net recoil pressure is zero, and the respiratory system is in a position of equilibrium.

DYNAMIC MECHANICAL PROPERTIES OF THE RESPIRATORY SYSTEM

The total nonelastic resistance of the lungs consists of the resistance of the airways to airflow (airway resistance), defined in terms of the driving pressure and the resulting rate of airflow, and the frictional resistance of the lung tissues to displacement during breathing (tissue resistance). Normally, tissue resistance makes up only 10% to 20% of the total pulmonary nonelastic resistance, but in diseases of the pulmonary parenchyma, it may increase considerably.

■ Airway Resistance

Much of our understanding of the physics of airflow and airway resistance dates back to the early part of the 20th century.[26] A large fraction of the resistance to airflow is in the upper respiratory tract, including the nose, mouth, pharynx, larynx, and trachea. During nasal breathing, the nose constitutes up to 50% of total airway resistance. During quiet mouth breathing, the mouth, pharynx, larynx, and trachea constitute 20% to 30% of the airway resistance, but they account for up to 50% of the total airway resistance when minute ventilation increases—during vigorous exercise, for example. Most of the remainder of airway resistance is in medium-sized lobar, segmental, and subsegmental bronchi up to about the seventh generation of airways.[27,28] Additional branching distally causes a progressive increase in the number of airways in any generation. While the caliber of individual airways in daughter branches compared to the parent branch is reduced, the total cross-sectional area of all airways in a given generation increases tremendously with successive generations along the tracheobronchial tree. Consequently, in the normal lung, the small peripheral airways, particularly those less than 2 mm in diameter, constitute only about 10% to 20% of the total airway resistance.[29]

Airway Caliber

The airways, like the pulmonary parenchyma, exhibit elasticity and can be compressed or distended. Therefore, the diameter of an airway varies with the transmural pressure applied to that airway—that is, the difference between the pressure within the airway and the pressure surrounding the airway. The pressure surrounding intrathoracic airways approximates pleural pressure, since these airways are tethered to the parenchymal tissue and are exposed to the expansive forces that are active in overcoming the elastic recoil of the lung.[1]

Airway resistance varies inversely with lung volume. As the lung volume increases, the elastic recoil forces of the lung increase; the traction applied to the walls of the intrathoracic airways also increases, widening the airways and decreasing their resistance to airflow. Conversely, at low lung volumes, the transmural airway pressure is lower and airway resistance increases.[30,31] If the elastic recoil of the lung is reduced—by destruction of alveolar walls in pulmonary emphysema, for instance—the transmural airway pressure at any given lung volume decreases correspondingly; the airways are narrower and airway resistance is greater even though there is no disease of the airways per se.

The effects of a change in transmural pressure on airway caliber depend on the compliance of the airways—which, in turn, is determined by their structural support. The trachea, for example, is almost completely surrounded by cartilaginous rings, which tend to prevent complete collapse even when the transmural pressure is negative. The bronchi are less well supported by incomplete cartilaginous rings and plates, whereas the bronchioles lack cartilaginous support. All airways can be stiffened, albeit to different degrees, by contraction of smooth muscle in their walls.

In patients with airway disease, mucosal edema, hypertrophy and hyperplasia of mucus glands, increased elaboration of mucus, and hypertrophy of smooth muscle further compromise airway caliber and increase airway resistance.

Neural pathways and humoral mechanisms also are important in controlling airway smooth muscle tone and regulating airway caliber. Cholinergic parasympathomimetic stimulation originating from the vagus nerve and mediated through the release of acetylcholine causes airway smooth muscle contraction and airway narrowing. Noncholinergic parasympathetic activity may play a role in airway smooth muscle relaxation through the release of vasoactive intestinal peptide and the subsequent production of nitric oxide.[32] Beta-adrenergic receptors in bronchial smooth muscle activated by various sympathomimetic agents promote airway smooth muscle relaxation and airway dilatation.[33]

Pressure–Flow Relationships: Theoretical Considerations

In the lungs, pressure–flow relationships are extremely complicated because the airways consist of a system of irregular branching tubes that are neither rigid nor perfectly circular. For purposes of simplification, pressure–flow relationships in rigid tubes are generally regarded as a model for those in the airways.

The driving pressure that produces flow of air into and out of the lung must suffice to overcome friction and to accelerate the air. Acceleration in the lungs is of two types: local (i.e., changes in the rate of airflow with time when flow is initiated) and convective (i.e., acceleration of molecules of air over distance while flow is constant). The driving pressure required for convective acceleration is proportional to the gas density and to the square of the flow rate. It is important during expiration because, as air moves downstream from the alveoli toward the airway opening, the total cross-sectional airway diameter decreases; therefore, molecules of air must accelerate through the converging channels even though the overall flow rate remains unchanged. Also, the driving pressure that produces high expiratory flow rates at large lung volume serves for convective acceleration rather than for overcoming friction.[34,35]

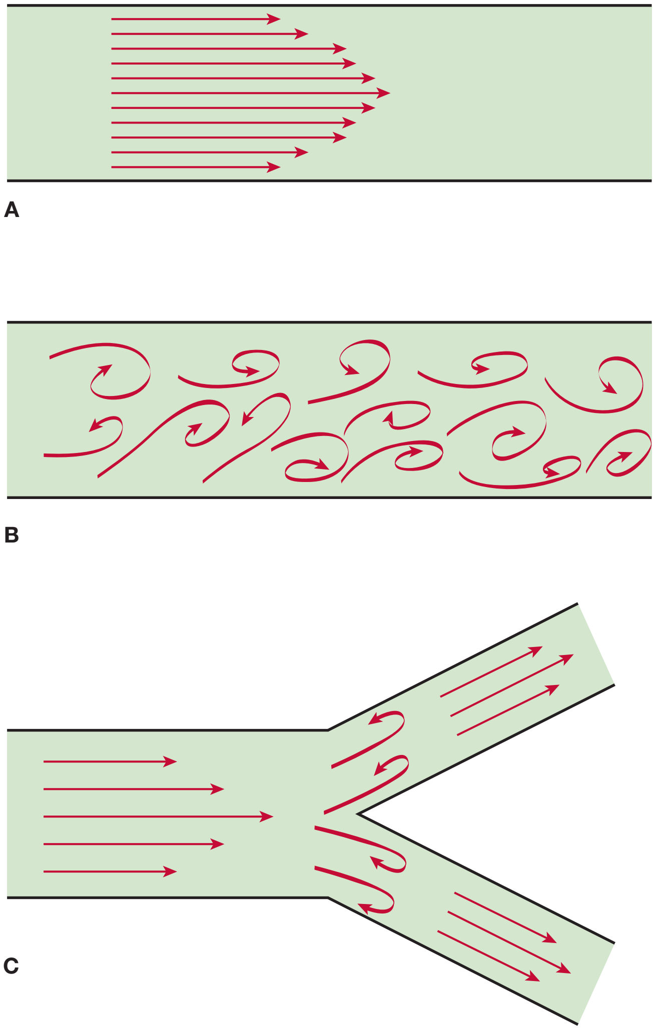

Figure 10-8 Patterns of airflow. **A.** Laminar flow. **B.** Turbulent flow. **C.** Transition flow that occurs at bifurcations.

The driving pressure required to overcome friction depends on the rate and the pattern of airflow. Two major patterns of airflow warrant special consideration: *laminar* and *turbulent*. Laminar flow is envisioned as streamlines of gas that flow parallel to the sides of the tube and "slide" over one another. Also, because the streamlines at the center of the tube move faster than those closest to the walls, the flow profile is parabolic (Fig. 10-8). The pressure–flow characteristics of laminar flow depend on the length (l) and the radius (r) of the tube, as well as the viscosity of the gas (η) according to Poiseuille's equation:

$$\Delta P = \frac{\dot{V} 8 \eta l}{\pi r^4}$$

where

ΔP = the driving pressure (pressure drop between the beginning and the end of the tube)
$\dot{V}$ = the flow rate that the driving pressure produces
r = the radius of the tube

The critical importance of tube radius in determining the driving pressure for a given flow is apparent in the previously mentioned equation. If the radius of the tube is halved, the pressure that is required to maintain a given flow rate must be increased 16-fold. Laminar flow patterns occur only in small peripheral airways, where, because of the enormous overall cross-sectional area, flow through the individual airways is exceedingly slow.

Turbulent flow occurs at high flow rates and is characterized by a complete disorganization of streamlines, so that the molecules of gas move laterally, collide with each other, and change velocities. Under these circumstances, pressure–flow relationships change. In contrast to laminar flow, the rate of turbulent airflow is no longer proportional to the driving pressure. Instead, the driving pressure to produce a given rate of airflow is proportional to the square of flow and is dependent on gas density. Turbulent flow predominates in the trachea.

At lower flow rates during expiration—particularly at branches in the tracheobronchial tree, where flow in two separate tubes comes together into a single channel—the parabolic profile of laminar flow becomes blunted, the streamlines separate from the walls of the tube, and minor eddy formation develops. This is referred to as a mixed, or *transitional*, flow pattern. In a mixed pattern of airflow, the driving pressure for a given flow depends on both the viscosity and the density of the gas.

Whether airflow is laminar or turbulent is predictable from the Reynolds number (Re), a dimensionless number that depends on the average velocity ($\bar{v}$), the density of the gas (ρ), the viscosity of the gas (η), and the diameter of the tube (D), so that

$$\mathrm{Re} = \frac{\bar{v}\,\mathrm{D}\rho}{\eta}$$

In straight, smooth, rigid tubes, turbulence occurs when the Reynolds number exceeds 2000. Therefore, turbulence is most apt to occur when the average velocity is high, gas density is high, gas viscosity is low, and the tube diameter is large. Since most of the resistance to airflow in the normal lung is in large airways, where airflow is largely turbulent and where resistance is density dependent, breathing a mixture of 80% helium and 20% oxygen (a mixture that is 64% less dense than air) reduces the Reynolds number, favoring a conversion from turbulent to laminar flow. Consequently, airflow increases at a given driving pressure and airway resistance falls.[27]

Calculation of Airflow Resistance

The driving pressure along the tracheobronchial tree—that is, the difference between alveolar pressure and the pressure at the airway opening (mouth) that is required to produce a given rate of airflow into the lungs—provides a measure of the flow resistance of the airways, according to the equation

$$\mathrm{R_{aw}} = \frac{\mathrm{P_A} - \mathrm{P_{ao}}}{\dot{\mathrm{V}}}$$

where

$\dot{\mathrm{V}}$ = airflow (L/s)
$\mathrm{P_A}$ = alveolar pressure ($\mathrm{cmH_2O}$)
$\mathrm{P_{ao}}$ = airway-opening pressure ($\mathrm{cmH_2O}$)
$\mathrm{R_{aw}}$ = airway resistance ($\mathrm{cmH_2O/L/s}$)

Flow–Volume Relationships

Considerable insight into the flow-resistive properties of the airways can be obtained from the relationship between airflow and lung volume during maximal expiratory and inspiratory maneuvers.[36] In practice, a person inhales maximally to TLC; then exhales as forcefully, rapidly, and completely as possible to RV; and then returns to TLC by a rapid, forceful inhalation (Fig. 10-9). During the maximal expiration, the rate of airflow peaks at a lung volume that is close to the TLC; as the lung volume decreases and intrathoracic airways narrow, airway resistance increases, and the rate of airflow decreases progressively.

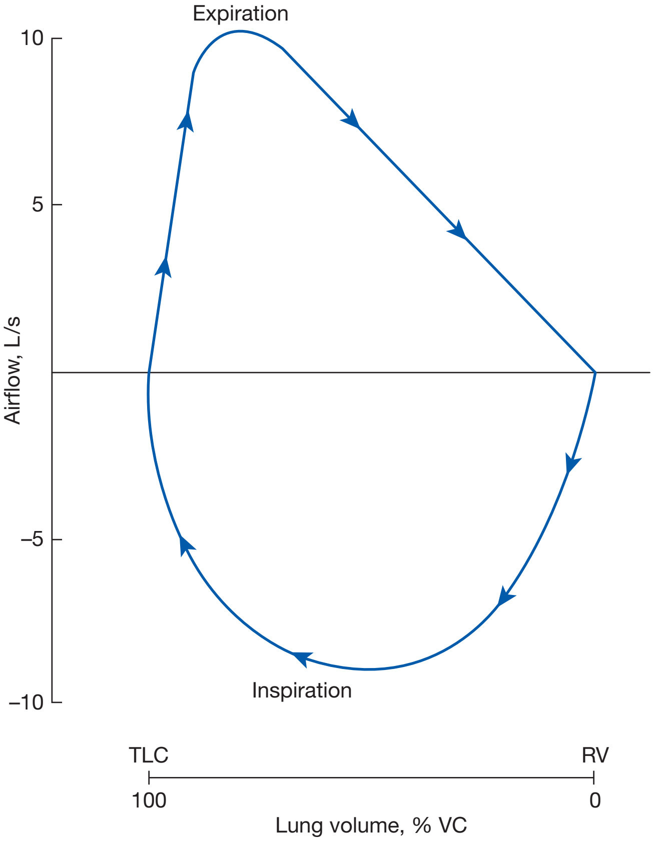

Figure 10-9 Maximal expiratory and inspiratory flow–volume loop.

During maximal inspiration, the pattern of airflow is different. Because of the markedly negative pleural pressure and large transmural airway pressure, the bronchi are wide, and their calibers increase further as lung volume increases. Consequently, inspiratory flow becomes high while the lung volume is still low and remains high over much of the vital capacity, even though the force generated by the inspiratory muscles decreases as they shorten.

A family of flow–volume loops is produced by repeating full expiratory and inspiratory maneuvers over the entire range of the vital capacity using different levels of effort (Fig. 10-10). The greater the effort exerted during inspiration, the greater is the rate of airflow over the entire range—that is, from RV to TLC. Similarly, during expiration, the rate of airflow increases progressively with increasing effort at large lung volumes close to TLC. At intermediate and low lung volumes, the rate of expiratory airflow reaches a maximum while the effort expended is only moderate; thereafter, airflow does not increase further despite increasing expiratory efforts.

Isovolume Pressure–Flow Curves

Separation of the effects of increasing effort from those of changes in lung volume on the rate of airflow during expiration can be accomplished by using isovolume pressure–flow curves (Fig. 10-11). During repeated expiratory maneuvers performed with varying degrees of effort, simultaneous measurements are made of airflow rate, lung volumes, and pleural pressure. For each lung volume the rate of airflow is plotted against the pleural pressure, as an index of the degree of effort.[37]

As expiratory effort is increased at any given lung volume, the pleural pressure increases toward, and then exceeds, atmospheric pressure; correspondingly, the rate of airflow increases. At lung

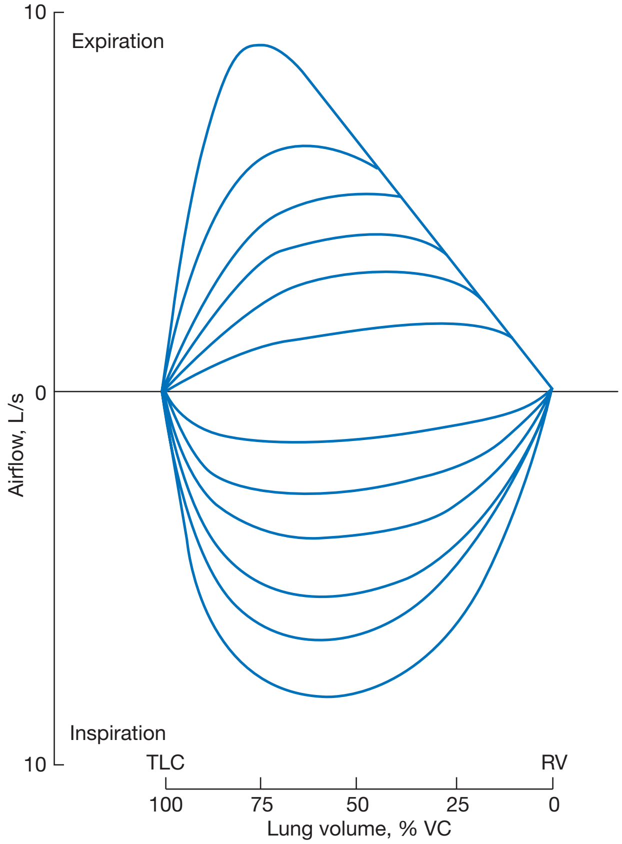

Figure 10-10 Series of flow–volume loops constructed from complete inspiratory and expiratory maneuvers repeated at different levels of effort.

volumes above 75% of the vital capacity, airflow increases progressively as pleural pressure increases; it is considered "*effort dependent*." In contrast, at lung volumes below 75% of the vital capacity, the rate of airflow levels off as the pleural pressure exceeds atmospheric pressure and becomes fixed at a maximum level. Thereafter, further increases in effort, and in pleural pressure, effect no further increase in the rate of airflow; at these lower lung volumes, airflow is considered "*effort independent*." Since the rate of airflow remains constant despite increasing driving pressure, it follows that the resistance to airflow must be increasing in direct proportion to the increase in driving pressure. This increase in resistance is attributed to compression and narrowing of large intrathoracic airways.

■ Equal Pressure Point Theory: Dynamic Compression of Airways

To illustrate the mechanisms that normally limit airflow during a maximal expiratory maneuver, it is useful to consider a model of the lung where the alveoli are represented by an elastic sac and the intrathoracic airways by a compressible tube, both enclosed within a pleural space (Fig. 10-12).[38]

At a given lung volume, when there is no airflow (as during breath holding with the glottis open), pleural pressure is subatmospheric, counterbalancing the elastic recoil pressure of the lung. The alveolar pressure (P_A), which is the sum of the recoil pressure of the lung and pleural pressure (P_{pl}), is zero (Fig. 10-12A). Since airflow has ceased, the pressure along the entire airway also is atmospheric.

At the same lung volume during a quiet expiration, pleural pressure is less subatmospheric. Since lung volume and the elastic recoil pressure of the lung are unchanged, alveolar pressure is now positive with respect to atmospheric pressure; airflow occurs. The alveolar pressure is gradually dissipated along the airway in overcoming resistance so that the pressure at the airway opening (P_{ao}) is zero.

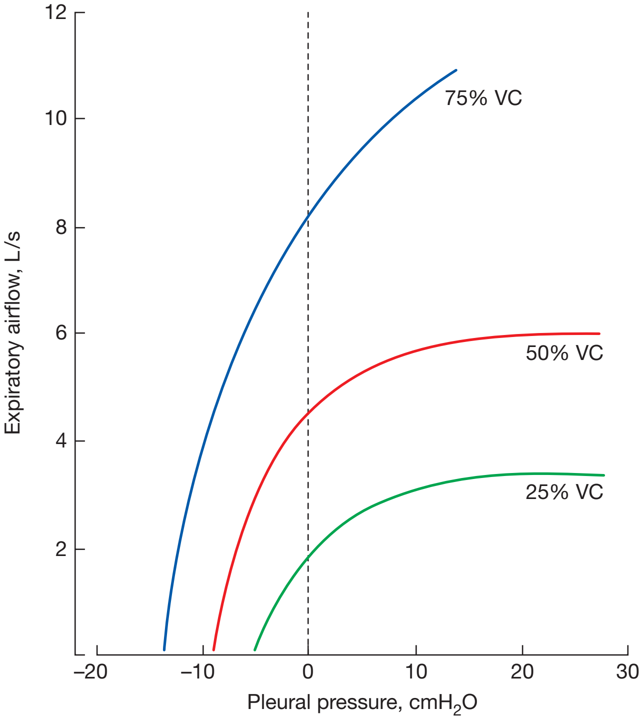

Figure 10-11 Isovolumetric pressure–flow curves. At lung volumes greater than 75% of the vital capacity, airflow is effort dependent; that is, airflow increases progressively with increasing effort. At lower lung volumes, airflow is effort independent—that is, airflow becomes fixed at a maximum level and does not increase despite further increases in effort.

All along the airway, however, the airway pressure exceeds pleural pressure, and the transmural pressure is positive; the airways remain open, and flow continues (Fig. 10-12B).

A forceful expiration raises pleural pressure above atmospheric pressure and further increases alveolar pressure (Fig. 10-12C). Airway pressure again falls progressively from the alveolus toward the airway opening. But at some point along the airway—the *equal pressure point*—the drop in airway pressure is equal to the recoil pressure of the lung; intraluminal pressure and the pressure surrounding the airways are equal and the same as pleural pressure. Downstream (i.e., toward the airway opening) the transmural pressure is negative, because the intraluminal airway pressure is less than pleural pressure; the airways are subjected to dynamic compression.

The equal pressure point divides the airways into two components arranged in series: an *upstream segment*, from the alveoli to the equal pressure point, and a *downstream segment*, from the equal pressure point to the airway opening. With increasing expiratory effort, as the pleural pressure becomes more and more positive with respect to atmospheric pressure, the equal pressure point moves upstream. Once maximum expiratory flow is achieved, the position of the equal pressure point becomes fixed in the region of the lobar or segmental bronchi. Further increase in pleural pressure by increasing expiratory force simply produces more compression of the downstream segment without affecting airflow through the upstream segment.

The driving pressure of the upstream segment—that is, the pressure drop along the airways of that segment—is equal to the elastic recoil of the lung. The maximum rate of airflow during forced expiration ($\dot{V}_{max}$) can be expressed in terms of the elastic recoil pressure of the lung (P_L) and the resistance of the upstream segment (R_{us}), as follows:

$$\dot{V}_{max} = \frac{P_L}{R_{us}}$$

Measurements of the rate of airflow during force expiration form the basis of many tests used to assess the flow-resistive properties of

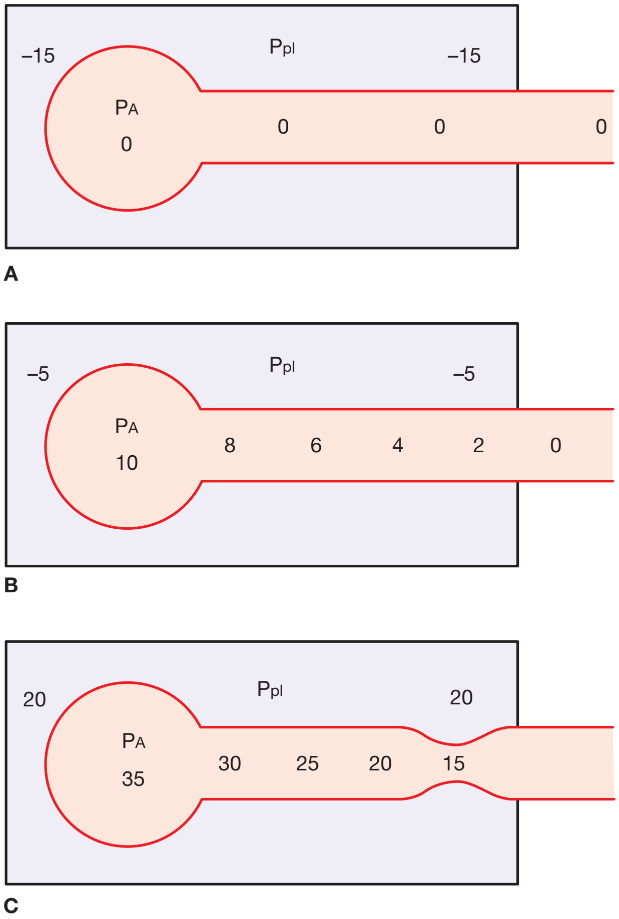

Figure 10-12 Schema of the distribution of pleural, alveolar, and airway pressures at rest and during expiration, illustrating the equal pressure point concept. **A.** End expiration. **B.** Quiet expiration. **C.** Forced expiration.

the lung. It is evident, however, that the maximum rate of expiratory airflow depends on many factors: The lung volume at which airflow is determined; the force of expiration (particularly at high lung volumes [i.e., above 75% of vital capacity]); the elastic recoil pressure of the lung; the cross-sectional area of large airways; the collapsibility of large intrathoracic airways; and the resistance of small peripheral airways.

■ Wave Speed Limitation Theory

An alternative explanation for airflow limitation during forced expiration is based on principles of wave speed theory.[39] The wave speed theory proposes that flow is limited by the velocity of propagation of pressure waves along the wall of the tube. The velocity of propagation (v) varies proportionally with the cross-sectional area of the tube (A) and with airway stiffness. At a site where the linear velocity of gas molecules equals the velocity of propagation of pressure waves, that is, wave speed, a choke point develops, preventing further increases in flow rate. The flow rate at wave speed is a function of the cross-sectional area of the tube at the choke point (A) and the stiffness of the choke segment (dP/dA), where P is the transmural airway pressure. Where choke points occur in the tracheobronchial tree depends on the lung volume: at large lung volumes, a choke point is situated in the vicinity of the lower trachea; at lower lung volumes, choke points develop more upstream along the bronchial tree. Extension of the neck exerts longitudinal tension and stiffens the trachea, increases wave velocity, and increases maximum expiratory flow rates at large lung volumes.[40]

MECHANICAL DETERMINANTS OF REGIONAL VENTILATION

The lung is not homogeneous, and the mechanical properties of all airways in a given generation and of all alveoli are not the same. This results in important nonuniformities of regional ventilation.

Pleural pressure in the upright person is more subatmospheric at the apex than at the base of the lung, because of the effects of gravity and the weight of the lung.[41] Pleural pressure topography and regional lung expansion are also determined by the shape of the chest wall and by the forces required for the lung to conform to the thoracic cavity shape.[9,42] The rate of increase in pleural pressure from top to bottom is approximately 0.25 cmH_2O per centimeter of vertical distance. Consequently, the transpulmonary pressure—that is, alveolar pressure minus pleural pressure—is greater at the top than at the bottom of the lung. Therefore, at most lung volumes, the alveoli at the lung apexes are larger (more expanded) than those at the lung bases (Fig. 10-13).

Because of regional variations in lung compliance, ventilation is not uniform, even in the normal lung. With the use of external scanners after the inhalation of a radioactive gas, such as ^{133}xenon, it has been demonstrated that within the range of normal tidal volume, lung units are better ventilated, and ventilation per alveolus is greater, at the bottom than at the top of the lung.[43] This is because alveoli near the top of the lung are positioned on the upper, flatter part of the pressure–volume curve and are less compliant than alveoli at the lung bases positioned on the lower, steeper portion of their pressure–volume curves.

At low lung volumes (i.e., near the RV), pleural pressure at the bottom of the lung actually exceeds airway pressure and leads to closure of peripheral airways (Fig. 10-13). During a breath taken from RV, air that enters the lungs first is preferentially distributed to the lung apexes.

The distribution of ventilation within the lungs and the volume at which airways at the lung bases begin to close can be assessed by the single-breath N_2 washout test[44] (see Chapter 31). This test requires a maximum expiration into an N_2 meter after a maximal inspiration of pure O_2 from RV; the changing concentration of nitrogen is plotted against expired lung volume (Fig. 10-14). Because the inspiration starts at the RV, the initial portion of the breath containing dead-space gas, rich in nitrogen, is distributed to alveoli in the upper lung zones. The rest of the breath, which contains only O_2, goes preferentially to lower lung zones. Consequently, the concentration of nitrogen is lower in the alveoli at the lung bases than in the alveoli at the apexes of the lungs.

During expiration, the initial portion of the breath consists of O_2 remaining in the large airways; it contains no N_2 (phase I). As alveolar gas containing N_2 begins to be washed out, the concentration of N_2 in the expired air rises to reach a plateau. The portion of the curve where the concentration of N_2 rises steeply is phase II. The plateau is phase III. Phase III depends on the uniformity of the distribution of ventilation in the lung. If gas enters and leaves alveoli throughout the lung synchronously and equally, phase III is flat. But when the distribution of ventilation is nonuniform, so that gases coming from different alveoli have different N_2 concentration, phase III slopes upward.

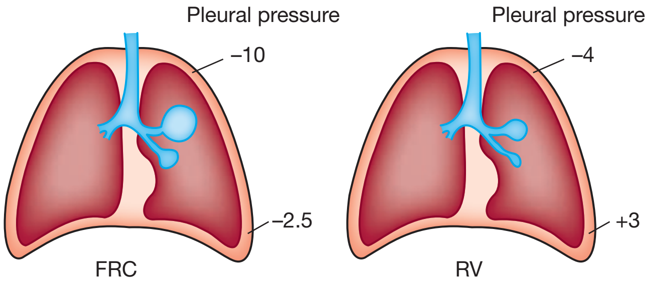

Figure 10-13 Pleural pressure gradients in the upright lung at FRC (left) and at RV (right). The effect of the gradient on alveolar volumes is shown schematically for each case.

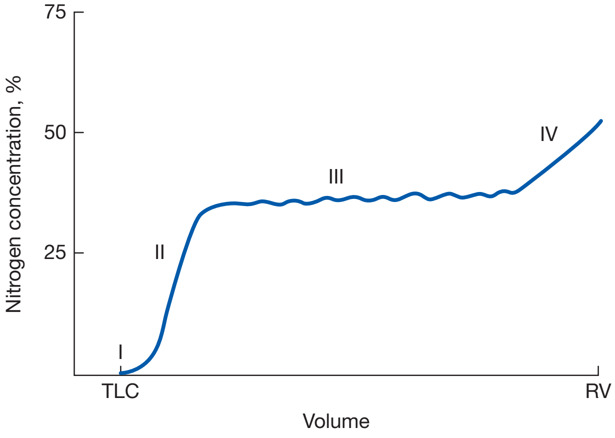

Figure 10-14 Tracing of expired nitrogen concentration during a slow expiration from TLC to RV after a full inspiration of pure O_2. The four phases are indicated. For further details, see text.

At low lung volumes, airways at the lung bases close; only alveoli at the top of the lung continue to empty. Since the concentration of N_2 in the alveoli of upper lung zones is higher than in the alveoli at the lung bases, the slope of the N_2–volume curve increases abruptly, marking the start of phase IV. The volume, above RV, at which phase IV begins is termed the *closing volume*.[45]

The closing volume increases with advancing age. With diseases of the peripheral airways closing volume may rise to levels above FRC. This results in lung units that are perfused but poorly ventilated leading to reductions in arterial oxygenation.[46,47]

■ Dynamic Compliance of the Lungs

The relationship between changes in volume and changes in pleural pressure during a normal breathing cycle is shown in Fig. 10-15. Airflow momentarily ceases at the end of expiration (A) and at the end of inspiration (C); the change in pleural pressure between these two points reflects the increasing elastic recoil of the lung as the volume of air in the lungs increases. The slope of the line connecting the end-expiratory and end-inspiratory points (AEC in the figure) on a pressure–volume loop provides a measure of the dynamic compliance of the lungs.

In normal persons, dynamic compliance closely approximates inspiratory static lung compliance and remains essentially unchanged even when breathing frequency is increased up to 60 breaths per minute. This indicates that lung units that are parallel with each other normally fill and empty uniformly and synchronously, even when airflow is high and the change in lung volume is rapid. The rate of filling and emptying of a lung unit depends on its time constant—that is, the product of its resistance and compliance. Lung units with high resistance and high compliance take longer to fill and empty more slowly compared to units with low resistance and low compliance. For the distribution of ventilation in parallel lung units to be independent of the rate of airflow, the resistance and compliance of these units must be matched so that the time constants of individual units throughout the lungs are approximately the same. The time constants of lung units distal to airways 2 mm in diameter are approximately 0.01 second, and fourfold differences in time constants are necessary to cause dynamic compliance to become frequency dependent.[29]

Patchy narrowing of small peripheral airways produces regional differences in time constants. At low breathing frequencies, when the rate of airflow is low, ventilation is fairly evenly distributed. As the breathing frequency increases, however, ventilation tends to be distributed to areas that offer the least resistance to airflow. Therefore, lung units fed by narrowed airways receive proportionally less ventilation than do areas of the lung where the airways remain normal; the change in pleural pressure required to effect the same change in overall lung volume increases. As a result, the dynamic compliance falls.

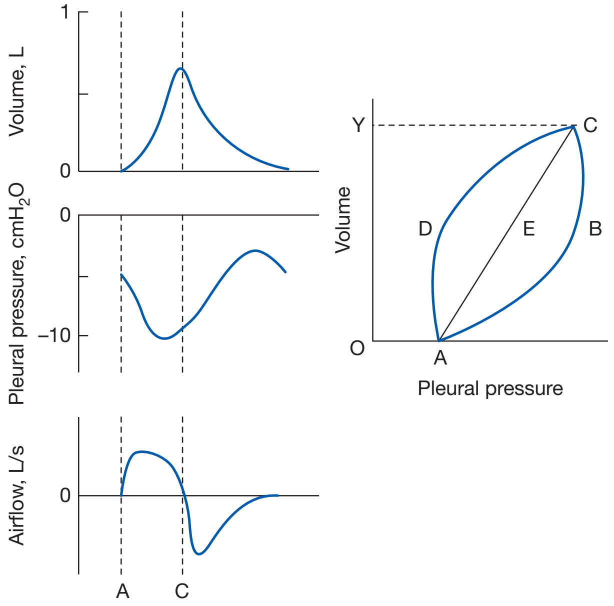

Figure 10-15 Individual tracings of tidal volume, pleural pressure, and airflow, taken simultaneously during a single complete breath, are shown on the left. The relationship between volume and pleural pressure is illustrated by the dynamic pressure–volume loop on the right. Dynamic compliance is determined as the slope of the line AEC. The work of breathing during inspiration to overcome the elastic forces of the lung is represented by the area of the trapezoid OAECY, and the work required to overcome nonelastic forces is represented by the area of the loop ABCEA. The loop AECDA represents the work required to overcome airflow resistance during expiration.

Measurements of frequency dependence of dynamic compliance are time-consuming and technically difficult. The test was thought to be potentially useful in the diagnosis of obstruction in small peripheral airways when results of other conventional tests of lung mechanics are still within normal limits.[48] However, it is rarely performed in pulmonary function laboratories.

WORK OF BREATHING

During breathing, the respiratory muscles work to overcome the elastic, flow-resistive, and inertial forces of the lungs and chest wall.[49] The elastic work of breathing is done to overcome the elastic recoil of the lungs and chest wall; the resistive work is done in overcoming the resistance of airways and tissues. The mechanical work of breathing can be determined by relating the pressure exerted across the respiratory system to the resulting change in volume, since the product of pressure (P) and volume (V) has the dimension of work, according to the equation:

$$\text{work} = \int P\,dV$$

Recordings of pleural pressure and lung volume changes during spontaneous breathing can be used to measure the work of breathing; the work of breathing performed on the lungs can be determined from the area of the dynamic pressure–volume loop (Fig. 10-15) and fractionated into its elastic and resistive components. During inspiration, the work done to overcome the elastic forces of the lung is determined from the area of the trapezoid OAECY (Fig. 10-15). The area of the loop ABCEA is the work in overcoming nonelastic forces during inspiration, and the area of the loop OABCY is the total work of breathing during inspiration.

Expiration during quiet breathing is passive since the elastic recoil of the lung suffices to overcome the expiratory airflow resistance. Some of the stored elastic energy is also used to overcome inspiratory muscle activity that persists into the expiratory phase of breathing. At high levels of ventilation and when airway resistance is increased, additional mechanical work during expiration is required to overcome nonelastic forces. Under these circumstances, the pleural pressure exceeds atmospheric pressure, and the loop AECDA extends beyond the confines of the trapezoid OAECY (Fig. 10-15).

The work of breathing at any given level of ventilation depends on the pattern of breathing. Large tidal volumes increase the elastic work of breathing, whereas rapid breathing frequencies increase the work against flow-resistive forces. During quiet breathing and during exercise, people tend to adjust tidal volume and breathing frequency to values that minimize the force and the work of breathing.[50] Similar adjustments are also seen in patients with pulmonary disorders. Patients with pulmonary fibrosis, which is characterized by an increased elastic work of breathing, tend to breathe shallowly and rapidly; those with airway obstruction and increased nonelastic work of breathing usually breathe more deeply and slowly.

The work done on the chest wall during breathing is calculated by subtracting the work performed on the lung from the total mechanical work of breathing. The total mechanical work of breathing cannot be readily measured during spontaneous breathing because the respiratory muscles that perform the work also make up part of the resistance offered by the chest wall. But the total mechanical work can be determined during artificial ventilation by using either intermittent positive airway pressure or negative pressure applied to the chest, provided that the respiratory muscles are completely at rest. For this determination, the change in lung volume is related to the pressure difference across the respiratory system—that is, differential pressure between the mouth and the body surface. Disturbances of the chest wall, such as kyphoscoliosis and obesity, increase the work of breathing severalfold.

■ Oxygen Cost of Breathing

To perform their work, the respiratory muscles require O_2. The O_2 cost of breathing, which reflects the energy requirements of the respiratory muscles, provides an indirect measure of the work of breathing.[51,52] The O_2 cost of breathing is assessed by determining the total O_2 consumption of the body at rest and at an increased level of ventilation produced by voluntary hyperventilation or CO_2 breathing. Provided there are no other factors acting to increase O_2 consumption, the added O_2 uptake is attributed to the increased metabolism of the respiratory muscles.

The O_2 cost of breathing in normal subjects is approximately 1 mL/L of ventilation and constitutes less than 5% of the total O_2 consumption. At high levels of ventilation, however, the O_2 cost of breathing becomes progressively greater. There is a dramatic increase in the O_2 cost of breathing at high levels of ventilation in some diseases of the lung, such as pneumonia, pulmonary fibrosis, and emphysema, and in disorders of the chest wall, such as obesity and kyphoscoliosis. The increase in the energy requirement of the respiratory muscles during increased ventilation, concomitant with a decrease in O_2 supply secondary to arterial hypoxemia, contributes to muscle fatigue, thereby limiting the amount of exertion that these patients can sustain.[3]

CHAPTER 11

Control of Ventilation

Frank J. Jacono
Atul Malhotra

INTRODUCTION

Breathing is a rhythmic motor act that is under both conscious and automatic control. The respiratory control system maintains numerous controlled variables within their homeostatic ranges but is also responsible for rapidly changing ventilation in response to often unpredictable stimuli. We will discuss the anatomy and physiology of the ventilatory control system, then address integrated responses and illustrative examples of adaptation and dysfunction in the setting of selected disease states.

ANATOMY AND PHYSIOLOGY

The respiratory control system, broadly speaking, comprises a controller, sensors, and a plant (Fig. 11-1). This hierarchical structure, in which there is central processing of afferent input, is important for coordinating respiratory movements with behaviors such as eating, speaking, and moving.[1] The controller is a neuronal network within the central nervous system (CNS), which is responsible for generating and modulating individual breaths and the overall breathing pattern. Often referred to as the respiratory central pattern generator (rCPG), the controller comprises reciprocally connected neuronal populations in the medulla and pons.[2,3] Neural output from the rCPG drives the activity of various motor neuron pools. Motor neurons in the spinal cord (e.g., phrenic and intercostal) innervate the respiratory pump muscles, while brain stem motor neurons innervate upper airway muscles. The so-called "plant" is an important component of breathing control and includes the CO_2 stores, which are made up of lung stores and circulating blood volume including hemoglobin. Closed loop feedback to the controller is supplied by chemoreceptors and mechanoreceptors.

The consistent cycling of the ventilatory pattern is generated spontaneously from the spatial and functional architecture of the rCPG. Intrinsic membrane properties of rhythmically active neurons within the rCPG are capable of producing automatic periodicity.[4] In addition, reciprocal (excitatory and inhibitory) synaptic connections between neuronal populations in the medulla and pons are believed to be critical for the automatic generation of the respiratory rhythm.[2,3]

The neural respiratory cycle comprises three phases (Fig. 11-2).[5] Inspiration (I) involves ramp-like increases in inspiratory motor neuron firing, which drive phrenic nerve activity throughout this phase. The first phase of expiration (E_1) is often called post-inspiration because inspiratory motor neurons are still active. Persistent inspiratory motor activity during E_1, which declines throughout this phase, acts to slow the exit of air from the lungs. Finally, during the second phase of expiration (E_2), expiratory muscles are typically electrically silent. During this phase of passive relaxation, gas is expelled as the lungs and chest wall return to their equilibrium state (i.e., functional residual capacity). However, under conditions where respiratory drive is increased, expiratory muscles including the internal intercostal and abdominal muscles become active during E_2. This notion is an example of how the central controller, influenced by sensory feedback, modulates and alters the integrated motor response of the system.

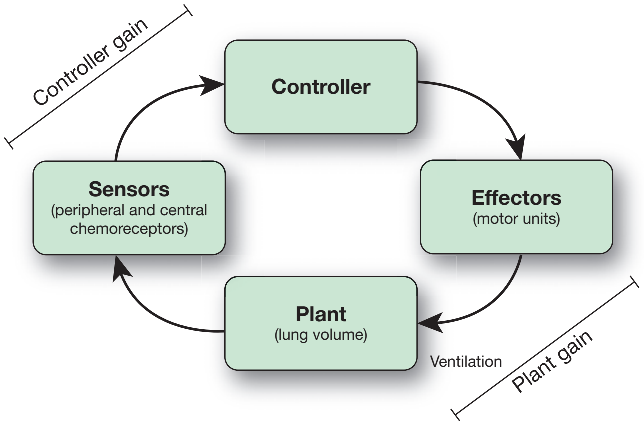

Figure 11-1 Block diagram of the respiratory control system.

■ Brain Stem

Within the medulla and pons, interconnected neuronal populations constitute a network that is considered necessary for the generation of the respiratory rhythm (Fig. 11-3).[2,3,6] This bilateral pontomedullary respiratory network, which is also responsible for control of the ventilatory pattern, contains the ventral respiratory column (VRC) and the pontine respiratory group (PRG). Afferent signals from lung mechanoreceptors and peripheral chemoreceptors enter the pontomedullary network via the nucleus of the solitary tract (nTS) in the dorsal respiratory group (DRG). The nTS has projections to both pontine and ventral medullary components of the central respiratory network. Taken together, the VRC, DRG, and PRG constitute the brain stem rCPG. The rhythmic output of the rCPG drives the activity of spinal phrenic, intercostal, and lumbar motor neuron pools that innervate the muscles of respiration. Other brain stem motor neurons exhibit respiratory modulation and control muscles of the upper airway. Finally, the rCPG is influenced by higher CNS structures, which allows for conscious control of the ventilatory pattern.

Several regions of rhythmically active neurons in the VRC represent the core circuitry of the rCPG. The pre-Bötzinger complex (pre-BötC) within the VRC is believed to be the main source of rhythmic excitation driving inspiratory premotor neurons and other brain stem circuits. Furthermore, the pre-BötC has been shown to manifest intrinsic rhythmic activity.[4] However, the mechanisms responsible for rhythmic inspiratory pattern generation are complex given the large number of modulatory inputs that converge on the pre-BötC compartment and are likely to manifest as the result of network properties. Neuronal populations in the Bötzinger complex (BötC) are the major source of expiratory network activity during normal breathing. Thus, BötC neurons are important for control of the transition between inspiratory and expiratory activities in the rCPG and maintenance of the rhythmicity of normal breathing.

Neurons within the PRG are critical for formation of normal resting breathing patterns. Functional connections between the pons and the rest of the rCPG modulate phase switching (onset and termination of inspiration). For example, the dorsolateral pons (dlPons) is a region within the PRG with respiratory-modulated neurons whose activity varies depending on the presence of vagal afferent feedback. In particular, eupneic breathing patterns are dependent on excitatory drive from pontine neurons to the VRC, emphasizing the importance of the spatial and functional architecture of the brain stem respiratory network. Medullary raphe nuclei likely represent a system of intermediate relays for signaling between the PRG and the

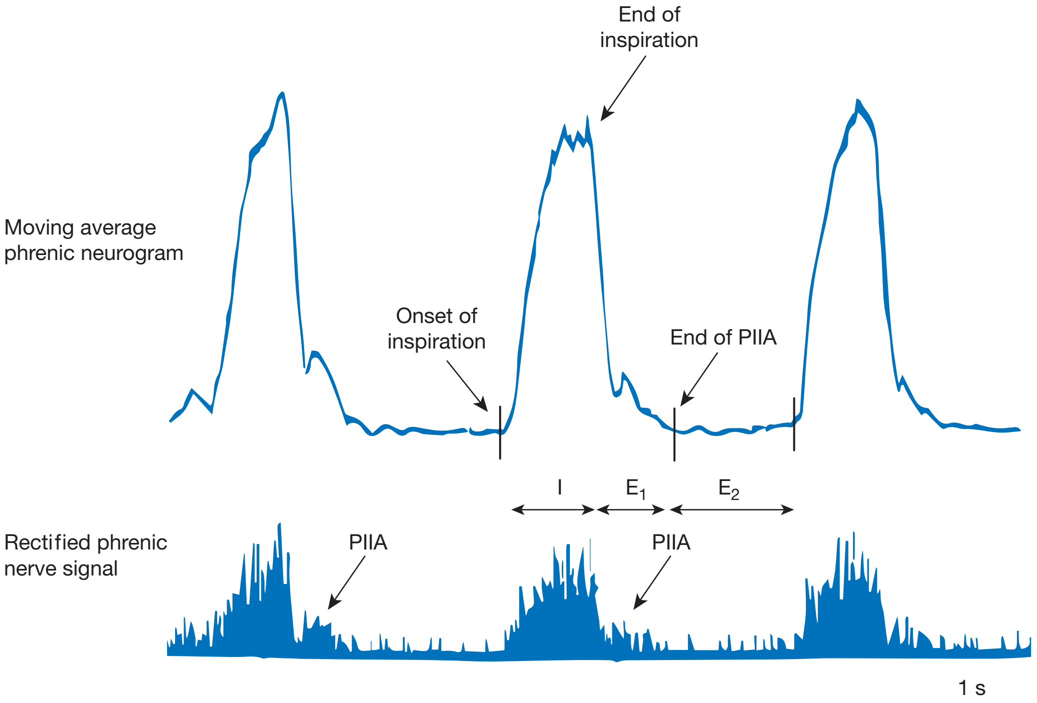

Figure 11-2 Recording of phrenic nerve activity (below) and its moving average (above), which highlights the three phases of the respiratory cycle: (1) Inspiration (I), (2) post-inspiratory activity (expiration, phase 1, E_1), and (3) late expiration (expiration, phase 2, E_2). PIIA, post-inspiratory inspiratory activity.

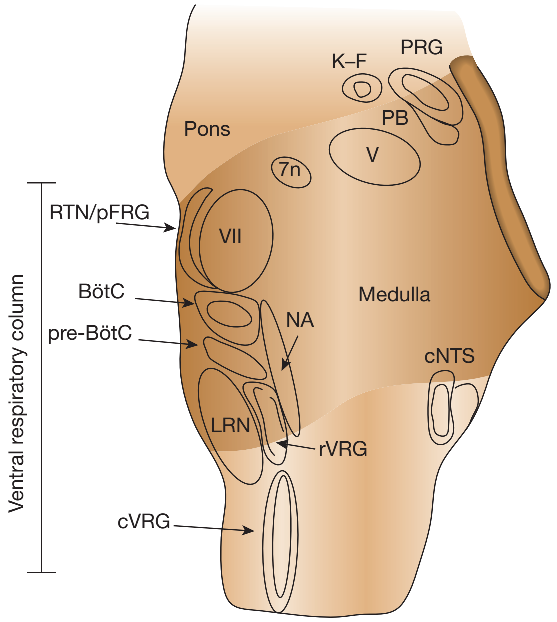

Figure 11-3 Overview of the respiratory central pattern generator (rCPG) within the brain stem. The ventral respiratory column (VRC) is orientated in the rostral-to-caudal direction. The VRC extends from the retrotrapezoid nucleus (RTN) adjacent to the rostral facial nucleus (VII) superiorly, to the caudal ventral respiratory group (cVRG) near the spinomedullary junction inferiorly. The main areas of rhythmically active VRC respiratory neurons are in the Bötzinger complex (BötC), pre-Bötzinger complex (pre-BötC), rostral ventral respiratory group (rVRG), and cVRG. The parafacial respiratory group (pFRG) overlaps anatomically with the RTN, and together these regions include intrinsically bursting neurons that may contribute to rhythm generation. Peripheral chemo- and mechanosensory inputs are transmitted to the nucleus of the solitary tract (nTS) in the dorsal respiratory group (DRG). The pontine respiratory group (PRG) includes the Kölliker–Fuse (K–F) and the parabrachial (PB) nuclei, which contain respiratory-modulated neurons. See text for additional details.

VRC. Transmission of an efference copy of ventilatory drive from the VRC is an example of one of these reciprocal connections. These medullary circuits may serve to maintain an overall level of rCPG activity. In addition, certain (particularly rostral) regions within the medullary raphe are chemosensitive, responding to local changes in carbon dioxide or pH, as well as exhibiting altered activity with stimulation of peripheral chemoreceptors.

The rostral ventral respiratory group (rVRG) region within the VRC comprises excitatory neurons that drive spinal phrenic and intercostal inspiratory motor neurons. This group of neurons is inhibited by the BötC during expiration and excited by the pre-BötC during inspiration. These rhythmically alternating influences, along with modulatory inputs from other areas of the pontomedullary network, are responsible for shaping and controlling the pattern of inspiratory rVRG activity. In contrast, the cVRG is thought to be the expiratory counterpart to rVRG activity.

Peripheral chemo- and mechanosensory inputs are transmitted to the nTS, which contains second-order neurons critical for reflex respiratory responses. For example, carotid body chemoreceptor and baroreceptor afferents terminate in the medial and lateral subnuclei of the nTS. Lung mechanoreceptors have projections to "pump cells" in the nTS, resulting in rhythmic activity of these cells which is modulated by lung inflation. The retrotrapezoid nucleus (RTN) is a site of central chemoreception. Chemoresponsive neurons within this region project to other areas of the rCPG and provide excitatory drive to the VRC and PRG. These sensory afferents, and the way in which they modulate breathing, will be discussed in subsequent sections. As part of the respiratory neural network, the nTS modulates breathing via projections to both pontine and ventral medullary components of the central respiratory network. In addition, neurons within the nTS receive inspiratory drive from the VRC and reciprocal pontine projections gate neuronal activity in the nTS.

■ Chemoreceptors

The carotid and aortic bodies are bilateral sensory organs that detect changes in arterial oxygen. Although very small in size, the reflexes initiated by these tissues (particularly the carotid bodies) are critical for evoking stimulation of breathing during hypoxemia.[7]

Stimulation of the carotid body by hypoxia (O_2 sensing) involves stimulus transduction and afferent nerve activation. Carotid bodies are composed of two cell types: type I and type II. Type I cells (also referred to as glomus cells) are of neural crest origin and are the putative oxygen-sensing cells. Glomus cells express a variety of neurotransmitters that play critical roles in sensory transmission of hypoxemia. Afferent nerve endings, whose cell bodies lie in the petrosal ganglion, form synaptic contacts with glomus cells and are responsible for afferent signaling to the CNS. The type II cells (also referred to as sustentacular cells) resemble glial cells, and they are thought to act primarily as supporting cells.

There are two main pathways by which the carotid body senses hypoxia, although which mechanism is primary remains an area of debate.[8–10] The first main pathway for oxygen sensing involves heme-containing proteins in the glomus cell (metabolic hypothesis). First proposed by Mills and Jobsis, and later supported by studies using exogenous carbon monoxide (CO), there is evidence that mitochondrial cytochrome(s) may act as potential O_2 sensors. Further, several nonmitochondrial heme proteins that are expressed in glomus cells, including NADPH oxidases and heme oxygenase-2 (HO-2), have been proposed as potential oxygen sensors. Finally it has been suggested that hypoxia leads to the formation of iron-containing compounds via chelation as part of the transduction process, although the putative proteins and downstream signaling pathways responsible for afferent nerve activation are not well defined.

The second general mechanism by which hypoxia leads to depolarization of glomus cells is via inhibition of an O_2-sensitive, membrane-bound K^+ channel. This pathway for sensory transduction is based on the neuronal phenotype of the glomus cells and is referred to as the membrane hypothesis. Glomus cells express a variety of O_2-sensitive K^+ channels including outward rectifiers, Ca^{2+}-activated K^+ channels, human-ether-a-go-go (hERG), and twin pore-acid–sensitive K^+ (TASK) channels.[11] There is published evidence supporting and refuting aspects of both the metabolic and membrane hypotheses. Most likely, both pathways complement each other and work in concert to facilitate oxygen sensing by glomus cells. For example, it has been proposed that with increasing severity of hypoxemia, additional pathways are activated, allowing the carotid body to respond to a wide range of arterial oxygen levels.

Regardless of the mechanism(s) involved, hypoxic sensing ultimately leads to a Ca^{2+}-dependent release of neurotransmitters from glomus cells. These signaling molecules activate nerve endings in the carotid sinus nerve leading to an increase in afferent nerve activity (sensory transmission). The carotid body expresses several classes of neurotransmitters, including (1) biogenic amines (acetylcholine [Ach], dopamine, norepinephrine, and 5-hydroxytryptamine), (2) neuropeptides (enkephalins, substance P, and endothelins), (3) adenosine triphosphate (ATP), (4) amino acids (e.g., GABA), and (5) gas transmitters (CO and nitric oxide, NO). Some of the transmitters (e.g., ACh, substance P, ATP) stimulate whereas others (e.g., dopamine, enkephalins) inhibit carotid sinus nerve activity. Identifying which transmitters are primarily responsible for hypoxia-induced afferent nerve activation under physiologic conditions remains an area of active research, and it is possible that corelease of multiple molecules, acting in concert, may ultimately be responsible for sensory excitation by hypoxia. While the carotid body is the primary peripheral chemoreceptor responsible for oxygen sensing, carbon dioxide also stimulates the carotid body, but the mechanisms are not fully understood. Finally, the interaction of the central and peripheral chemoreceptors is still debated, but recent evidence supports a hyperadditive model whereby the gain of one group of chemoreceptors can increase the responsiveness of the other (e.g., carotid body stimulation increases the gain of the central chemoreceptors).[12]

■ Mechanoreceptors

The lung, chest wall, and respiratory muscles all contain mechanoreceptors, which provide closed-loop feedback to the rCPG. This afferent input regulates minute ventilation independent from chemical drive. In addition, mechanoreceptor reflexes modulate the respiratory pattern on a breath-by-breath basis by enhancing or terminating inspiration. Afferent axons from lung mechanoreceptors are contained within the vagus nerve, but the importance of these receptors to control of respiration in awake, adult humans is likely small. Additional mechanoreceptors in the respiratory muscles and chest wall have central projections that travel in spinal nerves and the spinal cord. These receptors are important to coordinating the breathing pattern during trunk twisting and during movement between the upright and supine positions.

Several broad categories of mechanoreceptors are relevant to ventilatory control.

Lung stretch receptors are present in the airway smooth muscle of the distal airways. These slowly adapting receptors are stimulated by lung inflation. Afferent signaling following activation of these receptors tends to terminate inspiration without altering the slope of the inspiratory ramp, as well as to promote expiratory activity. Slowly adapting receptors in the lung are the afferent fibers responsible for the Hering–Breuer reflex, which describes the termination of inspiration (promotion of inspiratory-to-expiratory phase switching) that occurs as a result of lung inflation. In addition, expiratory prolongation and occasional apneas that occur with large and sustained inflation of the lung are a manifestation of this reflex.

Rapidly adapting receptors respond to changes in airway mechanical properties that accompany lung inflation and deflation and become more active as the rate of airflow increases. These receptors are also activated by stimuli that induce bronchospasm, edema, or mucus secretion. For example, they produce cough and laryngeal narrowing in response to stimulation by dust, ammonia, histamine, and other agents, as well as in response to increases in inspiratory airflow. These lung mechanoreceptors are primarily located in the epithelial and submucosal layers of the larger airways, accounting for their sensitivity to inhaled agents. Finally, rapidly adapting receptors lead to increased respiratory frequencies at low lung volumes, due to afferent signaling that increases inspiratory neural activity during lung deflation.

Bronchial J receptors are named for their juxtacapillary location. These lung mechanoreceptors project centrally through unmyelinated (in contrast to the first two types) fibers and respond to pulmonary vascular congestion associated with increases in pulmonary artery and capillary pressure. Stimulation contributes to the increase in respiratory frequency and a decrease in tidal volume in response to pulmonary edema.

Bronchial C receptors are named for their sensitivity to capsaicin and are located in the airway wall. Similar to type J receptors, these lung receptors project centrally through unmyelinated-fibers. Activation of C fibers with capsaicin or bradykinin produces cough and a rapid, shallow breathing pattern. Unlike other lung receptors described here, bronchial C receptors are relatively insensitive to mechanical stimulation and changes in lung volume.

Muscle spindles transduce muscle length. The diaphragm has few if any muscle spindles, but these mechanoreceptors are plentiful in the intercostal muscles. Muscle spindles tend to augment breathing when activated.

Muscle tendon organs are located in series with muscle fibers in the tendon and are activated as muscle fibers generate force. Thus, these mechanoreceptors sense the efficiency of force generation and inhibit breathing when activated. The central tendon of the diaphragm contains tendon organs, as do the tendons of accessory muscles of respiration.

The rib cage joints and upper airways (larynx, pharynx, and nasal cavity) also contain receptors that impact control of ventilation. For example, cold air stimulation of the pharynx initiates the cough reflex and can reduce the ventilatory response to carbon dioxide.

Upper Airway and Pump Muscles

The upper airway muscles are described more completely elsewhere but are addressed briefly here for completeness. The pharyngeal dilator muscles can be broadly classified into those with phasic activity (burst with inspiration) and tonic activity (constant activity throughout the respiratory cycle). The genioglossus is a frequently studied muscle as it is a representative phasic muscle that is readily accessible for intramuscular recordings and is controlled by the hypoglossal motor nucleus. The genioglossus is a major dilator muscle, which serves to protrude the tongue and protect pharyngeal patency in the face of collapsing perturbations. The tensor palatini, in contrast, is a representative tonic muscle controlled by trigeminal motor branches. Recent insights from recordings of single motor units have defined the complexity of these various muscles and provided insights into brain stem control in humans.[13] Although robust activity of the pharyngeal dilator muscles has been observed in obstructive sleep apnea patients during wakefulness, the fall in activity of these muscles at sleep onset likely contributes to a propensity to upper airway collapse in susceptible individuals. Some data also support evidence of structural neural remodeling and reinnervation of genioglossus muscle fibers, suggesting that neural injury also may be present in patients with sleep apnea.[14] Given the recent realization that sleep apnea has multiple underlying mechanisms, there is likely a subset of OSA patients who have dysfunction in upper airway muscles as a major pathogenic factor. Various approaches are being considered to augment upper airway dilator muscle activity, including the possibility of pharmacologic manipulation of hypoglossal output or electrical stimulation of the hypoglossal nerve. Pharmacologic targets are being defined through careful studies of premotor inputs to the hypoglossal motor nucleus, although, as yet, no human trials have shown clear augmentation of genioglossus activity with pharmacotherapy. While the role of hypoglossal nerve stimulation in treating sleep apnea remains incompletely defined, recent work highlights the clinical promise of this approach.[15,16]

STABILITY OF VENTILATORY CONTROL: LOOP GAIN

Loop gain is an engineering term that is used to define the stability or instability of a negative feedback control system. Overall loop gain can be thought of as the integration of controller and plant factors and is thus the product of controller gain and plant gain (Fig. 11-1). A system with a high loop gain is prone to instability, whereas a system with low loop gain is intrinsically stable. The concept of loop gain can be considered in the context of the thermostat analogy, which is a common example of a negative feedback control system designed to regulate room temperature. Situations that lead to oscillations in room temperature can be considered analogous to situations in humans in which CO_2 levels fluctuate. For example, a highly sensitive thermostat is one that responds to trivial fluctuations in room temperature with major changes in output from the air conditioner or furnace; thus, a very sensitive thermostat will lead to marked fluctuations in room temperature. By analogy, exquisite sensitivity of chemoreceptors will contribute to marked fluctuations in CO_2 levels. Another example of elevated loop gain is a furnace that is too powerful such that a minor drop in room temperature leads to major elevations in room temperature as a result of the output of the furnace. By analogy, if a minor increase in Pa_{CO_2} led to major increases in ventilation yielding marked reductions in Pa_{CO_2}, the system would be considered unstable—that is, elevated loop gain. Thus, situations that lead to fluctuations in room temperature can be considered to understand the factors underlying CO_2 fluctuations in the human.

In the case of ventilation, the propensity for CO_2 fluctuations is a function of an individual's loop gain. That is, an individual with a high loop gain is prone to developing periodic breathing or Cheyne–Stokes respiration (CSR), even with minimal perturbation. On the other hand, an individual with low loop gain will maintain relatively stable breathing patterns even with major perturbations. The mechanism underlying a high loop gain can be highly varied but can generally be considered due to an elevation of either controller gain or plant gain. Controller gain is also known as chemoresponsiveness, which includes chemosensitivity (i.e., how much chemoreceptors fire with a given CO_2 stimulus) in addition to the actual change in ventilation for a given CO_2 stimulus (e.g., which includes upper airway patency). In addition, plant gain describes the efficiency of CO_2 excretion, that is, how much the CO_2 actually changes for a given change in ventilation. Individuals with congestive heart failure are at risk of CSR likely due to elevated chemoreflex gain as well as elevated plant gain compared with matched controls.

The delay in the circulation, sometimes defined by a mixing gain, also is an important factor in determining breathing pattern. The ability for the human ventilatory control system to develop instabilities is a result of chemoreceptors being located in the brain stem and carotid bodies rather than in the lung. Circulatory delay can also contribute to an unstable breathing pattern, although most studies suggest that marked prolongation of circulatory delay is not present in CSR patients with congestive heart failure compared to heart failure patients without CSR. In classic Guyton experiments, several-minute delays were occasionally required to induce periodic breathing in dogs; such circulatory delays are beyond the range of what occurs in humans even in pathologic states (e.g., end-stage congestive heart failure). Thus, circulatory delay is considered necessary but not sufficient to induce periodic breathing or CSR. Some interventional studies suggest improvements in sleep apnea with reduction in circulatory delay, emphasizing the importance of this variable in some individuals.[17]

The measurement of loop gain is cumbersome currently, as it requires overnight experimental measurements and considerable expertise. However, the concepts are useful in a qualitative manner even if quantitative data are not available. In addition, efforts are ongoing to simplify the loop gain measurement to determine expeditiously which patients may respond to particular interventions.[18] The importance of loop gain is receiving increasing attention given the recognition of its importance in obstructive sleep apnea,[19] central sleep apnea,[20] periodic breathing at high altitude, and other conditions. Indeed, manipulation of loop gain using interventions such as oxygen or acetazolamide can lead to improvements in sleep apnea in small physiologic studies.[21,22] Thus, further work on ventilatory loop gain is required to define the optimal diagnostic and therapeutic approaches.

CONTROL OF VENTILATION IN HEALTH AND DISEASE: ILLUSTRATIVE EXAMPLES

The afferent, efferent, and central neural systems described earlier respond to a variety of challenges that affect both normal individuals and patients with respiratory disease. These pathophysiologic changes will affect the level of ventilation, the respiratory rhythm, or both. The impact of ventilatory control on specific disease states is addressed as appropriate in relevant sections elsewhere in this text. Following are illustrative examples that are considered to highlight how the respiratory control system adapts in clinically important conditions.

Ventilatory Acclimatization to Oxygen Disturbances

There are many pathophysiologic mechanisms that cause hypoxemia, and it has been well known for more than a century that hypoxia stimulates the respiratory and cardiovascular systems.[23] Heymans et al., among others, demonstrated the importance of carotid body chemoreceptors for the hypoxic ventilatory response.[22,25] Comroe and Mortimer[6] established the idea that arterial chemoreceptors are the dominant O_2-sensitive chemoreceptors for cardiopulmonary control. Elimination of the carotid and aortic body chemoreceptors elicits hypoventilation and essentially obliterates the acute ventilatory response to hypoxemia.[26] Therefore, it has been assumed that central O_2 sensitivity may not play a major role in this response.[27] In fact, chronic hypoxia reportedly has a depressive effect on the brain, limiting its response to further hypoxia. This hypoxic depression spreads rostrocaudally in the brain; and it may be the result of slowed removal of inhibitory neurotransmitters like GABA during hypoxia due to the buildup of lactic acid in the brain. However, in some experimental preparations, hypoxia continues to stimulate ventilation and the cardiovascular system in the absence of carotid body chemoreceptors, suggesting that other arterial chemoreceptors or sites in the CNS must be sensitive to hypoxia.[6] Focal hypoxia produced by cyanide in the medulla excites sympathoexcitatory neurons,[28] and experimental evidence supports central O_2 sensitivity in the C1 sympathoexcitatory region of the rostral ventrolateral medulla, the posterior hypothalamus, the preBötC, and the nucleus tractus solitarius.[26]

Hypoxic Ventilatory Response

The hypoxic ventilatory response is characterized by discrete, time-dependent mechanisms that depend on the severity, duration, and pattern of hypoxic exposure. A reduction in the partial pressure of oxygen produces an immediate increase in ventilation mediated through the peripheral chemoreceptors.[29] While the ventilatory response to hypoxia is independent of the source of hypoxemia, the brain has multiple time domains of O_2 sensitivity that can elicit different ventilatory responses to acute versus chronic hypoxia. Furthermore, this ventilatory response has several unique forms of respiratory plasticity.[30]

Acute and Chronic Exposure to High Altitude

The hypoxic and hypobaric environment encountered at high altitude results in a reduction in the available inspired oxygen (inspiratory partial pressure of O_2 [$P_{I_{O_2}}$]). Acute exposure to altitude results in hypoxemia, which produces an immediate increase in minute ventilation mediated through the peripheral chemoreceptors and characterized by an increase in frequency (respiratory rate) and amplitude (tidal volume). With ongoing exposure, ventilation continues to increase for several days resulting in a sustained gradual decrease in arterial P_{O_2}. Chronic exposure to high altitude, lasting from several hours to months, results in acclimation. This adaptation to high altitude is characterized by a gradual rise in minute ventilation with a time course depending on the altitude. In humans, at very high altitudes (~8000 m), this process may take at least 30 days. At less extreme altitudes, complete adaptation may be achieved in less than 10 days. However, in one study, ventilation and arterial oxygenation were noted to be greater than during the initial ascent to 3800 m after 8 weeks.[31] In addition, there is an increase in CO_2 sensitivity with exposure to altitude. In people living in high altitude for long periods of time, the P_{CO_2} falls to the lower level of normal or even less (Fig. 11-4).[31]

A number of physiologic mechanisms of ventilatory acclimation to hypoxia have been identified. They include (1) plasticity in O_2 sensitivity of the carotid body chemoreceptors, (2) the CNS integration of peripheral O_2-sensitive reflexes (e.g., carotid body chemoreflex), (3) plasticity of CNS mechanisms of acute O_2 sensing, and (4) the CNS integration of other nonchemoreflex ventilatory control pathways such as reflexes from pulmonary vagal chemoreceptors or respiratory rhythm generators.[26,32,33] For example, hypoxia-inducible factor-1 (HIF-1) is a key regulator of O_2-sensitive gene expression in the brain, and increases in HIF-1 have been identified in respiratory nuclei of the CNS as soon as 1 hour after hypoxemia. Hence, O_2 sensing by HIF-1α could be involved in the ventilatory acclimation to high altitude by increasing the expression of genes with products known to modulate the hypoxic ventilatory response (see Chapter 91 for further discussion).[34]

■ Oxygen-Induced Hypercapnia in Chronic Obstructive Pulmonary Disease

In severe chronic obstructive pulmonary disease (COPD), transient falls in ventilation and respiratory acidosis have been reported with breathing 100% oxygen for 20 minutes.[35–37] Initially CO_2 retention with oxygen treatment was thought to result from the suppression of the hypoxic drive mediated by carotid chemoreceptors.[38] Subsequently, additional mechanisms have been shown to contribute to oxygen-induced hypercapnia in COPD as follows:

(1) The increase in oxygen tension in lung units with low ventilation/perfusion (V/Q) ratios can blunt hypoxic pulmonary vasoconstriction in these low-V/Q lung units, thus diverting perfusion away from high-V/Q lung units yielding higher dead space; (2) the Haldane effect, which refers to the reduction in hemoglobin affinity for CO_2 with the binding of oxygen to hemoglobin. With increased

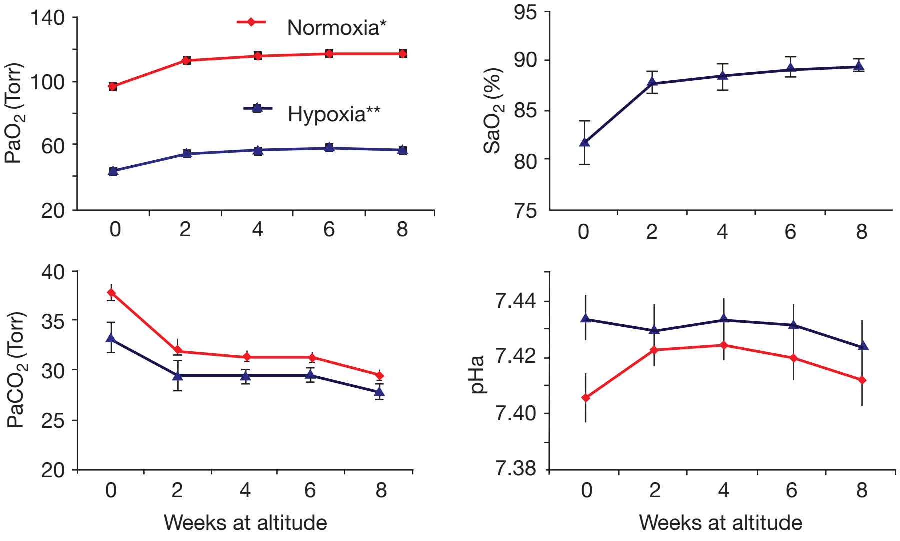

Figure 11-4 Arterial oxygenation increases and arterial CO_2 decreases during time at altitude. These changes persist in normoxia, indicating hyperventilation. pHa is partially compensated during acclimatization. *Normoxia is from data collected breathing at sea level. **Hypoxia is from data collected breathing at 3800-m altitude. *(Data from Hupperets MD, Hopkins SR, Pronk MG, et al. Increased hypoxic ventilatory response during 8 weeks at 3800 m altitude. Respir Physiol Neurobiol. 2004;142(2–3):145–152.)*

blood oxygen levels, the Haldane effect promotes dissociation of carbon dioxide from hemoglobin and leads to a small increase in Pa_{CO_2}; (3) suppression of hypoxic drive as mentioned above—data on P_{CO_2} recruitment threshold in intubated COPD patients support a change in sensitivity of the CNS to CO_2 during hyperoxia; (4) some patients with acute exacerbations of COPD are susceptible to the development of severe hypercapnia due to sleep deprivation that is common in acute illness; patients with associated obstructive sleep apnea might be susceptible since they have high sleep drive and are likely to lose the wakefulness drive to breathe at sleep onset upon initiation of therapy—for example, patients during acute exacerbations of COPD will commonly be sleep deprived and will typically fall asleep once they receive the anxiolytic and antidyspnea effects of oxygen therapy[37,39]; and (5) increases in Fi_{O_2} that occur as minute ventilation falls when supplemental oxygen is delivered noninvasively via conventional, low-flow nasal cannula. Actual delivered Fi_{O_2} is a function of inspiratory flow demand and room air entrainment; thus, higher oxygen tensions result as ventilatory drive falls for any reason. Occasionally vicious cycles can occur whereby supplemental oxygen leads to a rise in CO_2 level, which contributes to a further increase in oxygen level due to a resultant decrease in inspiratory flow with reductions in room air entrainment.

Understanding these mechanisms has clinical implications, as maintaining the arterial oxygen saturation between 87% and 92% may be a safer approach in patients with a history of respiratory disease and is unlikely to compromise tissue oxygen delivery.

■ Responses to External Mechanical Loads and Bronchoconstriction

In response to external mechanical loads, several compensatory factors act to maintain ventilation:[40] (1) *Responses intrinsic to the respiratory muscles*. The force that the muscle develops for a fixed electrical input depends on the length of the muscle (the force–length relationship). As the muscle shortens, less force is developed. The generated force also decreases as the velocity of shortening increases (force–velocity relationship). With external mechanical impediments (loading), both the magnitude and the velocity of shortening tend to decrease. (2) *Reflex effects.* At the spinal level, less shortening of the inspiratory muscles increases the signal from muscle spindles that, in turn, augments contraction of these muscles. During loading, afferent information from pulmonary mechanoreceptors also changes. Since tidal volume is depressed, inspiratory duration tends to be prolonged (Hering–Breuer inspiratory terminating reflex), but this mechanism is of little importance in humans. (3) *Conscious responses.* Loads increase neuromuscular output even in the face of a constant chemical drive. The magnitude of the increase is related to the severity of the mechanical load. This aspect of load compensation is abolished by anesthesia. Furthermore, the intensity of this load-compensating mechanism is variable, and it is reduced in some chronic lung disease like COPD.

While external loading is used experimentally, major differences exist between the neural responses to bronchoconstriction and external loading. In particular, inspiratory muscle activity increases during bronchoconstriction, even in anesthetized animals. Bronchoconstriction increases breathing frequency via reflex changes in respiratory timing. Expiratory duration (especially the second phase of expiration) shortens more than inspiratory duration. In asthma-induced bronchoconstriction, rapidly adapting receptors are stimulated by mechanical changes in the airways and by substances such as histamine and bradykinin.

■ Response to Exercise

The exercise ventilatory response is the most frequently engaged ventilatory response in everyday life.[30] Despite the increase in CO_2 production and O_2 utilization during exercise, ventilatory control mechanisms normally keep arterial P_{CO_2} and $[H^+]$ remarkably constant over a wide range of metabolic rates.[41] This pattern is achieved by graded increases in minute ventilation ($\dot{V}_E$) as the rate of CO_2 production increases and acts to minimize acidosis that would impair cellular function. This response is tightly controlled; respiratory alkalosis does not typically develop during moderate exercise in normal subjects, although it occasionally occurs in pathophysiologic states. With increased intensity of exercise, oxygen demand outstrips oxygen supply, anaerobic pathways start to operate, and blood lactate levels increase. With exertion above this anaerobic threshold, the exercise-induced metabolic acidosis becomes more marked due to a net increase in lactic acid production. As a result, high-level exercise results in a large increase in ventilation to enhance carbon dioxide excretion and minimize acidemia (see Chapter 32 for additional discussion).

The minute ventilation required to maintain acid–base equilibrium during exercise is defined by (1) the amount of carbon dioxide produced as a result of metabolism ($\dot{V}_{CO_2}$), (2) physiologic dead space, and (3) the set point at which P_{CO_2} is regulated by the respiratory control system. There is an incomplete understanding of the reflexes responsible for controlling how pulmonary ventilation matches the increases in metabolic demand during exercise without appreciable changes in arterial blood gas composition. The magnitude of oscillations in ventilation is directly related to metabolic CO_2 production. Thus, it has been proposed that a blood-borne signal helps in the coupling of metabolic production of CO_2 and ventilation. Neurally mediated signals from exercising muscles and from higher brain centers are also likely important in the ventilatory response. Finally, this response is responsible for meeting the increased need for oxygen consumption by exercising limb and respiratory muscles.

The initial phase of the exercise response is a rapid increase in ventilation. Proposed sources include signals arising from the cortex (so-called feedforward control), temperature increases, afferent signals arising as a result of muscle contraction (locomotor muscle afferents and respiratory muscle metaboreflex), accumulation of catecholamines, and increases in potassium in the venous blood.[42] There is also evidence that the abrupt initial increase in ventilation at the onset of exercise is a learned response. That is, the primary drive to breathe at the start of exercise will augment respiration in anticipation of impending metabolic needs based on past exercise experiences.[43] Chemoreceptor feedback may act in concert with the feedforward stimulus to minimize disruptions in homeostasis as the intensity of exercise increases. In addition, there is capacity for modulation and plasticity of the mechanisms controlling breathing during exercise. For example, serotonergic modulation of descending drive is a mechanism for long-term modulation of exercise hyperpnea, which may be important in individuals with underlying cardiorespiratory disease.[44]

■ Disturbances of Respiratory Rhythm

Congenital central hypoventilation syndrome (CCHS), occasionally referred to as *Ondine's curse*, is a rare neurologic disorder characterized by inadequate breathing during sleep and, in more severely affected individuals, also during waking periods. Patients congenitally lack or have poor chemosensitivity to both hypercapnia and hypoxia and suffer from inadequate ventilation. More than 90% of patients with CCHS have an increased polyalanine repeat expansion mutation (PARM) in the paired-like homeobox 2B (PHOX2B) gene. Other cases of CCHS are the result of non-PARM mutations of the PHOX2B gene. Most cases are the result of a de novo mutation, although patients may have a family history of the disorder. There is a correlation with the number of polyalanine repeat expansion genotype and the need for continuous ventilatory support. The disease typically presents in childhood, but rare adult-onset cases have

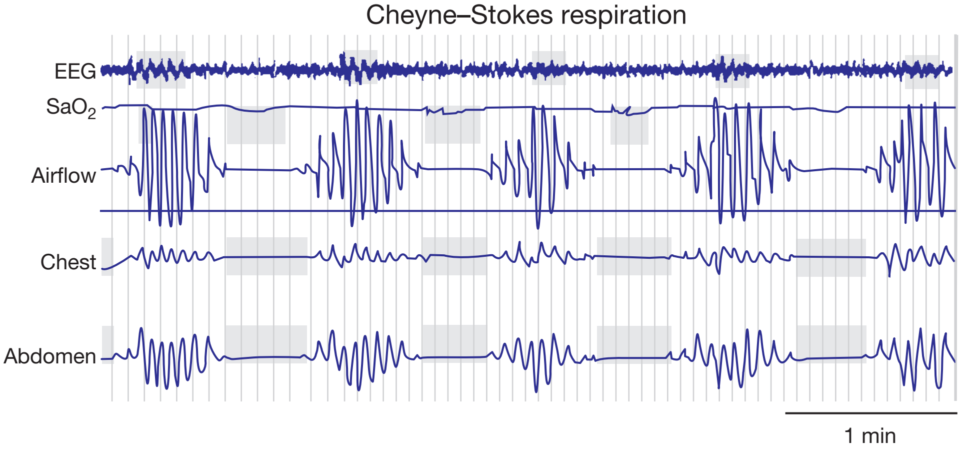

Figure 11-5 An example respiration in a patient with Cheyne–Stokes breathing. Note the characteristic crescendo/decrescendo pattern of breathing, long circulation time (each oxygen desaturation corresponds to the previous apnea), and arousal occurring at the peak of respiratory effort.

been reported.[45] A number of conditions are associated with CCHS and reflect the autonomic nervous system dysregulation, including Hirschsprung disease (about 20% of cases) and tumors of neural crest origin (neuroblastomas). While PHOX2B is considered to be the disease-defining gene in CCHS, these patients may have other protein-altering mutations including mutations in the *RET* gene which encodes the RET receptor tyrosine kinase, as well as the genes encoding, brain-derived neurotrophic factor (BDNF), endothelin 1 and endothelin 3.

Rett syndrome is a neurodevelopmental disorder that occurs almost exclusively in females. After a period of initially normal development, affected patients experience loss of speech and purposeful hand use, stereotypic hand movements, gait abnormalities, and breathing abnormalities among others. Most cases result from mutations in the gene encoding methyl-CpG-binding protein 2 (Mecp2). Loss of Mecp2 function is associated with an irregular breathing pattern. The implicated mechanism has not been established but may be related to widespread hyperexcitability in respiratory-related regions in the brain stem. Apnea that occurs during wakefulness is typically central, although it may be obstructive. These events may be isolated or precede or follow hyperventilation. During apneic episodes, the child may stare quietly ahead or smile and appear happy with no evidence of distress, despite severe cyanosis.

Cheyne–Stokes breathing is one form of periodic breathing characterized by a cyclic rise and fall in ventilation with recurrent periods of apnea or near apnea (Fig. 11-5). It was first observed in patients with cardiac or CNS disease, but it has since been reported in seemingly normal humans. The appearance of Cheyne–Stokes breathing can occur during wakefulness, although often masked by behavioral influences, but is more common during nonrapid eye movement (NREM) sleep. The period of the oscillations in ventilation in Cheyne–Stokes breathing often averages 60 to 90 seconds. Cycle length is related to the circulation time measured from the lung to a systemic artery and increases when circulation time is prolonged. Arousal tends to occur during the hyperpneic phase of the respiratory pattern, a finding that is often associated with paroxysmal nocturnal dyspnea in patients with heart failure.

Cheyne–Stokes breathing has not been consistently produced in animals by lesions in the CNS, but it has been shown to follow manipulations that are likely to produce unstable feedback control of breathing. Cheyne–Stokes breathing is seen in chronic heart failure, as well as in stroke and traumatic brain injury. A similar breathing pattern with a shorter cycle time (~15–30 seconds), often referred to as periodic breathing at high altitude, can occur in otherwise healthy individuals at high altitude during the acclimation period.

Sleep-Related Abnormalities of Ventilatory Control

Abnormal ventilatory patterns that can emerge during sleep are increasingly appreciated, including their associations with adverse neurocognitive and cardiovascular consequences. Ventilatory control instability may contribute to both central and obstructive sleep apnea. Indeed, sleep promotes breathing instability because it unmasks a highly sensitive dependence of the respiratory control system on chemoreceptor input. For example, the CO_2 reserve (i.e., the difference between the eupneic Pa_{CO_2} and that required to induce apnea) is labile during sleep and is reduced by hypoventilation, predisposing patients to the development of apneas.[46] Transient cortical arousals promote ventilatory overshoots, upper airway dilator muscle tone is reduced, and airway collapsibility is enhanced.[47] In addition, depending on the prevailing pharyngeal mechanics, anatomic factors may cause or contribute to sleep-related disorders. Thus, both basic and clinical investigators have focused on mechanisms that influence upper airway patency during wakefulness and sleep, along with ventilatory control stability during sleep (see Chapters 98–101 for further discussion).

There are a number of changes in ventilatory control that occur during sleep; however, most of the same basic mechanisms active during wakefulness are also relevant during sleep. During sleep, there is an elevation of the CO_2 set point (~45 mm Hg as opposed to 40 mm Hg during wakefulness), associated with reduced alveolar ventilation during sleep. In all stages of sleep, there is decreased ability to respond to increments in resistance–load and the work of breathing. Thus, narrowing of the upper airway during sleep is a factor contributing to the rise in Pa_{CO_2}.

Other ventilatory control mechanisms also are affected. Sleep apnea results in recurrent episodes of hypoxemia, which alter the hypoxic ventilatory response resulting in respiratory long-term facilitation (LTF).[48] LTF is a form of neuronal plasticity that is induced by exposure to intermittent hypoxia and causes a persistent increase in ventilation even when normoxia is restored.[30,49] Phrenic (innervating the diaphragm) and hypoglossal (innervating upper airway muscles) nerve activities are both increased. Whereas the impact of LTF on ventilatory stability remains uncertain in the context of sleep apnea at this time, experiments in preclinical animal models suggest that LTF has the potential for both stabilizing and destabilizing influences on breathing that warrant further investigation.[21,50,51]

Apnea is a cessation of airflow for at least 10 seconds and is probably the most common respiratory rhythm abnormality. Apneas occur often in premature infants and occasionally during sleep in healthy humans. Central apneas arise from complete or partial reductions in central neural outflow to the respiratory muscles during sleep (Fig. 11-6). In contrast to obstructive apneas, in which

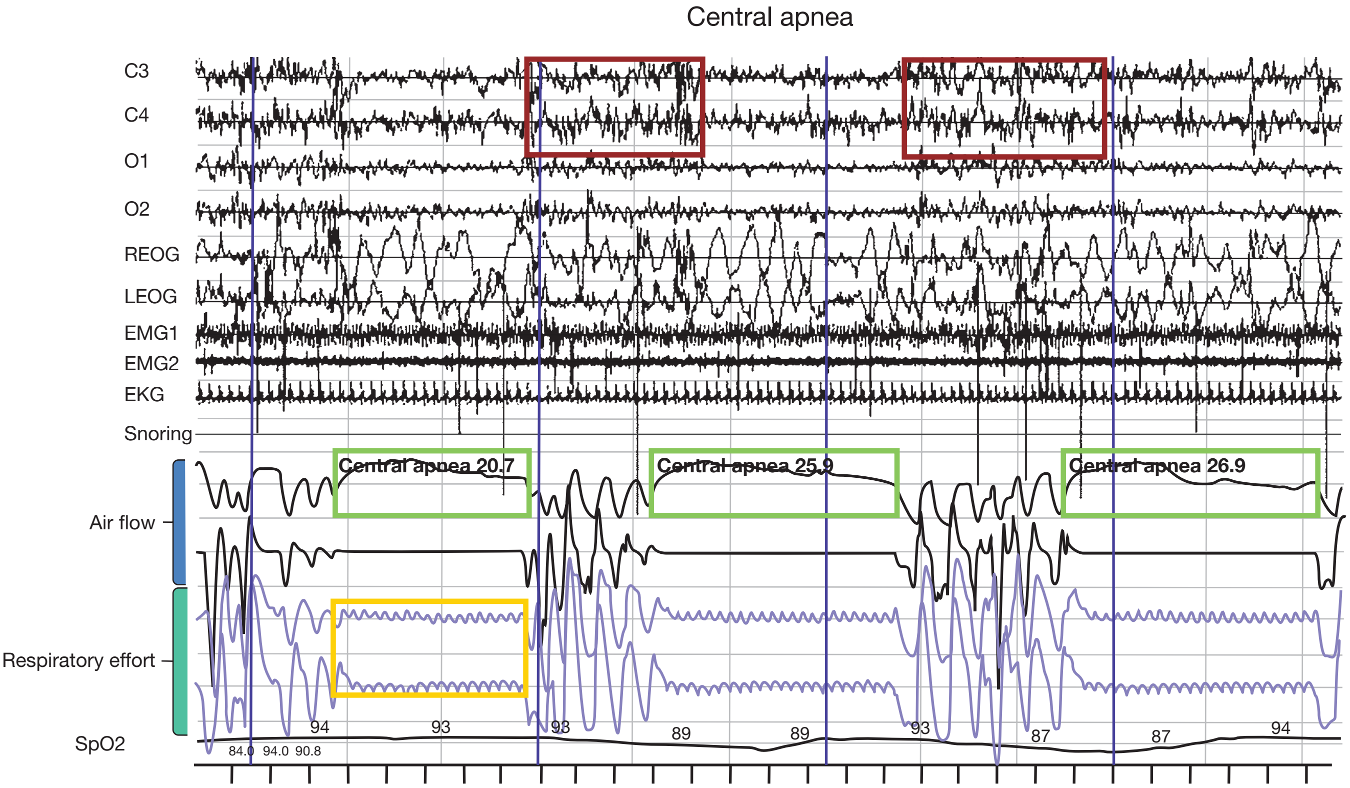

Figure 11-6 An example of respiratory pattern in a patient with central apneas. Note the typical characteristics of central apneas including absence of air flow by both nasal cannula pressure transducer and nasal–oral thermistor (durations in seconds), absence of respiratory effort measured with piezoelectric bands of the thorax and abdomen (orange box), associated oxygen desaturation corresponding to the previous apnea measured by pulse oximeter, and EEG arousal (red box) occurring after an apneic event. EEG channels (C3, C4, O1, O2); electrooculogram channels (REOG, LEOG), chin electromyogram (EMG1), bilateral tibialis anterior EMG2, EKG, snoring microphone.

inspiratory efforts are made against the occluded upper airway, no respiratory effort is generated during central apneas due to cessation of respiratory drive. Thus central apneas are distinguished from obstructive apneas by the absence of respiratory effort, which can be detected by routine monitoring techniques such as respiratory inductive plethysmography combined with assessment of nasal pressure.[20] Mechanisms that can produce central apneas include (1) reduced excitation of chemoreceptors as a consequence of hypocapnia and hyperoxia; (2) functional or actual structural medullary damage, which may result in a pattern of grossly irregular ataxic breathing; (3) loss of nonspecific respiratory excitatory stimulation (noise, light, tactile stimuli) in the absence of adequate chemical drive; and (4) active suppression of breathing by respiratory inhibitory reflexes, which is observed in a number of clinical situations including pharmacologic therapy with methadone and other opiate medications. Reflex inhibition may arise from the cardiovascular system, from the lung and chest wall, or from somatic and visceral afferents. For example, excitation of receptors located in the upper airway can, via the superior laryngeal nerve, trigger an apnea. Stimulation of J receptors in the lungs by inhaled irritants may produce temporary apnea.

Complex sleep apnea syndrome describes the appearance and persistence of central apneas or hypopneas in patients with obstructive sleep apnea upon successful restoration of airway patency. Patients with complex sleep apnea syndrome present with features of obstructive sleep apnea syndrome. However, when instability of upper airway tone is treated with positive airway pressure therapy, these patients exhibit unstable, chemosensitive ventilatory control leading to repetitive central apneas or periodic breathing during sleep.[52] Adaptive servo-ventilation, which provides both a minimum pressure to hold the airway open as well as a ventilatory assist to minimize persistent cycles of hypo- and hyperventilation, has emerged as an effective treatment in patients with normal systolic heart function. Noninvasive ventilation using bi-level positive airway pressure in the spontaneous-timed mode also may normalize ventilation in some patients.[53]

Central apneas may also occur in critically ill patients as a result of artificial ventilatory support. Application of positive pressure mechanical ventilation may result in a loss of respiratory drive and associated apneas both during and after periods of ventilatory support. This may occur despite normocapnic conditions and is more frequent during NREM sleep.[53] It is unclear whether these inhibitory effects are dependent on increases in tidal volume (e.g., Hering–Breuer mechanism) or are caused by a resetting of the inherent respiratory rhythm by the externally imposed ventilator frequency.[54,55] In addition, hypocapnia, oversedation, and the presence of CNS disease also will impact the prevalence of apneas during mechanical ventilation.

■ Dyspnea and Breathlessness

Dyspnea is defined as a subjective sensation of difficulty breathing, frequently termed “shortness of breath.” Under normal conditions, breathing is not noticeable. However, with increased demands (e.g., during exercise or with progressive cardiopulmonary disease), respiratory movements and forces become more perceptible. When sufficiently intense, respiratory efforts result in symptoms of dyspnea, and patients with lung disease may complain of dyspnea even at rest. The development of dyspnea is a warning signal that likely serves to protect the body from harm, but since dyspnea itself can become an incapacitating symptom, considerable attention has been given to its etiology.[56–61] Experiments using breath-holding techniques showed that hypercapnia and hypoxia decrease breath-holding times, supporting the idea that increased levels of chemical drive promote dyspnea. In contrast, increased lung volume (increased oxygen stores) lengthened breath-holding time. Other investigations identified that combined blockade of the phrenic and vagus nerves extends the time apnea can be voluntarily maintained, suggesting that signals from respiratory muscles contribute to the sense of dyspnea. Dyspnea also seems to be related to the effort (as a percentage of maximal capacity) required during breathing. In particular, dyspnea increases as the pressures required for tidal breathing grow greater or the maximal inspiratory pressure decreases (e.g., respiratory muscle paresis or fatigue). Taken together, these data suggest dyspnea may manifest as a sense of air hunger (breath holding) and/or as a sense of excessive effort (breathing against a resistance); it has been proposed that the two types of dyspnea are produced by different mechanisms with different anatomic pathways. In addition, cognitive and affective factors that determine the relative pleasantness and intensity of sensations may affect the level of dyspnea. A corollary discharge hypothesis has emerged whereby dyspnea is related to a mismatch between the central respiratory output and the actual achieved ventilation. During exercise, dyspnea is not profound since elevations in respiratory drive are associated with increases in the achieved minute ventilation. However, in situations where respiratory mechanics are impaired, for example, airway obstruction, dyspnea can be profound since high drive does not translate into high minute ventilation.

SUMMARY

Considerable progress has occurred in the area of control of breathing, both in terms of the basic underlying mechanisms as well as the clinical implications of the applied physiology. Given the ubiquitous nature of the associated diseases and conditions, further efforts into the basic and clinical aspects of this field will likely allow new therapeutic strategies to emerge.

CHAPTER 12

Sleep and Circadian Rhythms

Allan I. Pack

INTRODUCTION

Sleep and circadian rhythm are highly coupled processes. In the original formulation they were considered independent but interacting. Borbely and colleagues[1–4] posited that the circadian process (Process C) had a 24-hour rhythm that interacted with the sleep drive system (Process S) (Fig. 12-1). Process S is envisaged to be like an old-fashioned egg timer. The drive for sleep is at a very low level following the major sleep bout and increases progressively as wakefulness proceeds, i.e., the drive to sleep is related to the duration of prior wakefulness. Humans are programmed to sustain wakefulness for 16 hours but beyond this develop progressive performance impairments. During the day the drive to sleep is counteracted by an alertness signal from the clock. When this alertness signal declines later in the evening, the sleep drive is unopposed, and sleep ensues. During sleep the drive to sleep progressively declines, i.e., the egg timer is flipped, and the sands recover (Fig. 12-1). The situation is actually more complex than this since sleepiness occurs at two times of day, i.e., siesta time in early afternoon and late in the evening. While these processes were initially considered independent, they are not at a molecular level.[5,6] Core clock molecules increase their expression in brain when sleep is deprived.[7] Moreover, mutations of a clock-associated gene—DEC2, now called BHLEH41—result in short sleep in humans (<6 hours) without evidence of daytime performance impairment.[8,9]

In this chapter the basis of the clock is described, and the point made that the lung itself has a clock. Sleep is discussed and recent evidence reviewed that sleep alters gene transcription in the lung. The reader will get a background in sleep that will facilitate understanding the cardiopulmonary changes during sleep (Chapter 100) and sleep-disordered breathing (Chapter 98).

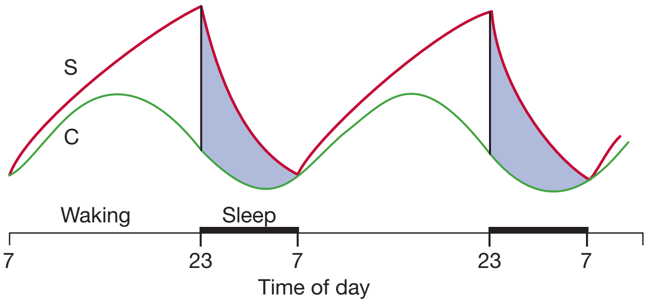

Figure 12-1 Two-process model of sleep/wake control. Behavioral state is controlled by the interaction between two processes: process C, the biological clock, and process S, the sleep homeostatic drive. The dark bar from 2300 to 0700 is the lights-off period. MOLECULAR MECHANISMS OF THE CLOCK

The fundamental principles of how the clock ticks are conserved across species, although the specific details, i.e., genes involved, vary between species.[10,11]

The original concept that the clock involves a distinct molecular mechanism came from identification of mutant fruit flies (*Drosophila*) with long circadian periods, flies with short circadian periods, and flies with no circadian rhythm.[12] Subsequently it was determined that these different flies had different mutations in the same gene, which was given the name period (per), i.e., the first clock molecule identified.[13] Later forward genetic studies identified another clock molecule in *Drosophila*, i.e., timeless.[14] The first mammalian clock gene was also identified by forward genetic studies, i.e., studying mice that had received a chemical mutagen—ENU—and had an abnormal circadian period.[15] This clock molecule is Clock and is a transcription factor.

In both *Drosophila* and rodents, the major mechanism of oscillation is a negative feedback loop (for mammalian model, see Fig. 12-2). There are also positive feedback loops. In mammals the main clock proteins are the 3 period proteins (per1, per2, and per3) and the two cytochrome proteins (cry1 and cry2). These proteins form a complex in the cytoplasm that enters the nucleus where they inhibit their own transcription that is controlled by the clock/BMAL1 complex (see Fig. 12-2). The degradation of the PER and CRY proteins is important in setting the period of the clock. The PER proteins are phosphorylated by enzymes such as casein kinase 1e and CKII. Once phosphorylated, the PER proteins are targeted for ubiquitination and degradation. In humans mutations in PER2, in the site in which it is phosphorylated[16] and also in CK1 delta,[17] lead to familial phase advance syndrome.[18] Individuals with this have marked phase advance going to sleep at 7:30 PM and waking up at 4:00 AM.

The other core feedback loop involves the orphan nuclear-receptor genes—Rev-Erbα/β and RORα/β. RORs activate BMAL1 while REV-ERBs repress BMAL1 and clock RORs and REV-ERBs are themselves targets of CLOCK-BMAL1 and are negatively regulated by the repressors CRY1 and 2 and PER, particularly PER2.

Thus, the clock is a cell-autonomous process and individual cells show circadian oscillation and clock mechanisms can be studied in vitro with cells in culture. The investigators who described this molecular mechanism in *Drosophila*—Jeff Hall, Michael Rosbash, and Michael Young—were awarded the Nobel Prize for this discovery.

SUPRACHIASMATIC NUCLEUS—THE MASTER CLOCK[19]

The master clock is in the suprachiasmatic nucleus (SCN) of the hypothalamus. It contains approximately 20,000 neurons. Destruction of this nucleus by lesioning results in the animal becoming arrhythmic, i.e., with no obvious circadian period.[20,21] The intrinsic period of the clock is not exactly 24 hours, and the clock is entrained each day to 24 hours by environmental cues. For the SCN, the main entrainment is by light/dark signals. There is a direct track from the retina to the SCN—the retino-hypothalmic tract. Moreover, there is a separate light-sensing mechanism in the eye for entrainment of the clock. This was identified in knockout mice that lacked rods and cones in the retina. While they were blind, there was normal entrainment of the circadian system to light/dark.[22,23] Subsequently, the basis of this light sensing mechanism was identified.[24,25] It is the pigment, melanopsin, that is in retinal ganglion cells scattered across the retina.[26–28] This pigment is particularly sensitive to light in the blue color range.[29] This has led to development of blue light boxes, blue light glasses, and glasses that filter out blue light to manipulate the light input to the clock. Following time zone change the output of the master clock is entrained to the new time zone by altered light/dark input. However, this re-entrainment is relatively slow with the clock adjusting only about 1 hour/day.

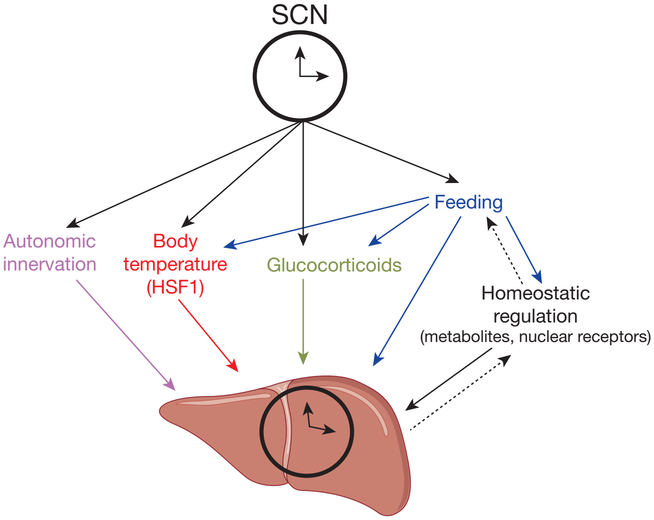
PERIPHERAL CLOCKS[11,30]

Once clock molecules were identified in mammals, the surprising result was that they were expressed in all tissues. It is now realized that there are functioning clocks in all tissues. These peripheral clocks are synchronized with signals from the master clock in the SCN. These peripheral clocks result in rhythmic expression of genes in each tissue, and some 3% to 10% of all mRNAs show rhythmic expression in different issues.[31] (The precise number of genes oscillating depends on the mathematical definition of oscillation such that some estimates of the number of mRNAs oscillating are higher than this.) Thus, there are substantial changes in the molecular functions of different organs at different times of day. The lung is no exception in this regard (see further below).

Peripheral clocks are not only controlled by signals from the master clock but also by signals that occur locally in the particular tissue (Fig. 12-3). Important signals include changes in autonomic nerve activity, body temperature, glucocorticoids and feeding pattern (see Fig. 12-3). Phase shifting of peripheral clocks occurs much more rapidly than for the SCN. Altering the feeding pattern of mice can produce large phase shifts in liver clocks without any effect on the rhythmic expression in genes in the SCN.[32,33]

There is also a molecular clock, not surprisingly, in the lung.[34,35] There is a clock in the Clara cells of the mouse bronchial epithelium.[36] As in other organs, there are a large number of genes that show diurnal changes in expression including genes involved in



SCN
Feeding
Autonomic innervation
Body temperature (HSF1)
Glucocorticoids
Homeostatic regulation
(metabolites, nuclear receptors)

Figure 12-3 There are peripheral clocks in all organs. This diagram is for liver, but there are also clocks in the lung (see text). The "master" clock is in the suprachiasmatic nucleus (SCN) of the hypothalamus. It sends signals to peripheral clocks to synchronize them. There is also local control of clocks by metabolites, etc. *(Reproduced with permission from Mohawk JA, Green CB, Takahashi JS. Central and peripheral circadian clocks in mammals. Annu Rev Neurosci. 2012;35:445–462.)*

extracellular matrix, cell cycle, and apoptosis.[37] Genes encoding inflammatory molecules such as chemokine ligands also show diurnal oscillation.[37] The immune response, which is such a critical function of the lung, is under circadian control.[38] Circadian rhythm of other functions of the lung are known to occur, including in FEV_1.[39] Circadian variation also occurs in asthma symptoms,[39] as do changes in the cellular content of bronchoalveolar lavage fluids in patients with mild asthma.[40]

The lung clock and, indeed, other peripheral clocks, are affected by hypoxia.[41] The transcriptional response to hypoxia is dependent on time of day. Exposure to hypoxia phase shifts clocks in a tissue-specific fashion, leading to asynchrony of rhythms of the clock in different tissues.[41]

The functioning of the lung clock is particularly relevant to lung cancer and to the immune response in the lung. A wide range of core clock molecules are epigenetically altered in a variety of lung tumors.[42] Moreover, disruption of the circadian rhythm promotes tumor growth in the lung.[43] This has been shown in a mouse model with lung adenocarcinoma. Physiologic perturbations to simulate jet-lag promoted growth of the lung tumor.[43]

The immune system in the lung has a circadian rhythm.[44] This applies to both innate and adaptive immune responses. The role of the clock in immune responses was the topic of a recent NIH workshop.[45] Different aspects of the immune response are regulated by the circadian system. The best-documented aspect is the regulation of pro-inflammatory cytokines.[46] Trafficking of myeloid and lymphocyte subsets are also regulated by the clock.[47] The clock is also involved in the differentiation and maturation of specific subsets of immune cells.[48,49]

CLOCK GENES AND PHARMACOLOGY[50,51]

Given that a large part of the genome is regulated by clocks, it is not surprising that clock mechanisms can affect actions of drugs. The absorption of many commonly used drugs shows time-of-day effects, as do drug metabolism and drug excretion.[50,51] For example, there is a circadian variation in gene expression of several members of the cytochrome P450 system, the main system for drug oxidation, in liver.[31] Protein levels of cytochrome P450 also oscillate across the day,[52] and there is a circadian rhythm of the activity of all cytochrome P450 enzymes.[53]

Thus, efficacy of specific drugs can vary with time of day. The anticoagulant effect of heparin, for example, varies with time of day.[54] When heparin is administered by constant intravenous infusion, the anticoagulant effect varies at different times of day.[54]

The concept of *chronopharmacology* is most developed for cancer therapy. Levels of plasma 5-fluorouracil vary across the day when the drug is delivered at the same rate.[55–57] There is a circadian variation of the pharmacokinetics of 5-fluorouracil.[58] Clinical trials show that treatment efficacy and toxicity of a chemotherapeutic regimen for metastatic colorectal cancer are enhanced using appropriate chronotherapy compared to constant infusion.[59]

Thus, time of day circadian effects need to be considered in pharmacology. There is a developing interest in this aspect when considering optimal drug regimens.

SLEEP AND ITS STAGES

It is now realized that sleep is universal. While definitions of sleep in mammalian species are based on the electroencephalogram, behavioral criteria[60,61] have led to identification of sleep in many species. In particular, a sleep state has now been identified in *Drosophila*,[62,63] zebrafish,[64] and most recently in the worm *C. elegans*.[65] Thus, all model systems are available to study sleep. There are already data showing that molecular mechanisms regulating sleep are conserved across species.[66]

While there is a suggestion that there are different stages of sleep in *Drosophila*,[67] rapid eye movement (REM) sleep has been recognized in mammals and birds. There is recent demonstration of a REM sleep state in zebrafish.[68] In mammals sleep is divided into two major types—non-REM (NREM) sleep and REM sleep.[69] REM sleep is a stage with the following: the brain is quite active with flurries of activity resulting in rapid eye movements; individuals waking from REM sleep recall their dreams; there is active paralysis of muscles apart from the diaphragm such that normal individuals do not live out their dreams. (Individuals with REM behavior disorder do enact their dreams since the atonia of REM sleep is no longer in place. This is a synucleinopathy, and a high percentage of individuals with REM behavior disorder go on to develop Parkinson's disease.[70]) There is also in REM autonomic instability with variations in heart rate and breathing pattern [see Chapter 100].) NREM sleep is divided into stages based on the electroencephalogram (Fig. 12-4). Originally four stages of NREM sleep were identified,

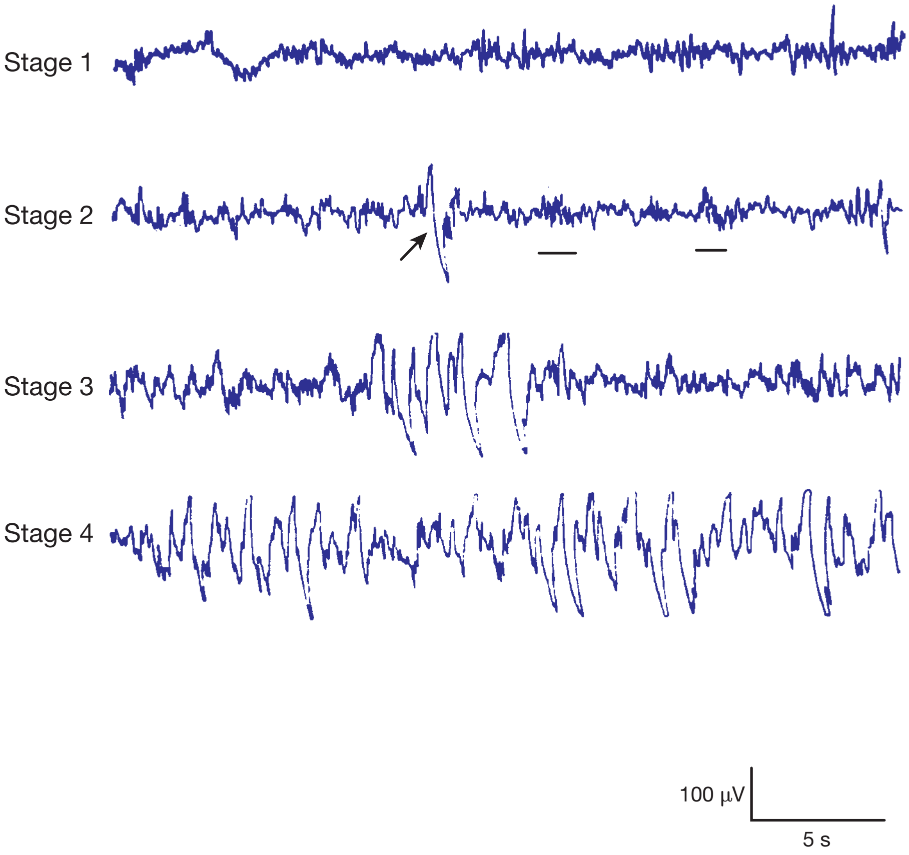


Figure 12-4 Electroencephalographic tracings recorded from a normal young adult demonstrating the four stages of NREM sleep. In the stage 2 recording, the arrow points to a characteristic K complex and the underlining to sleep spindles.

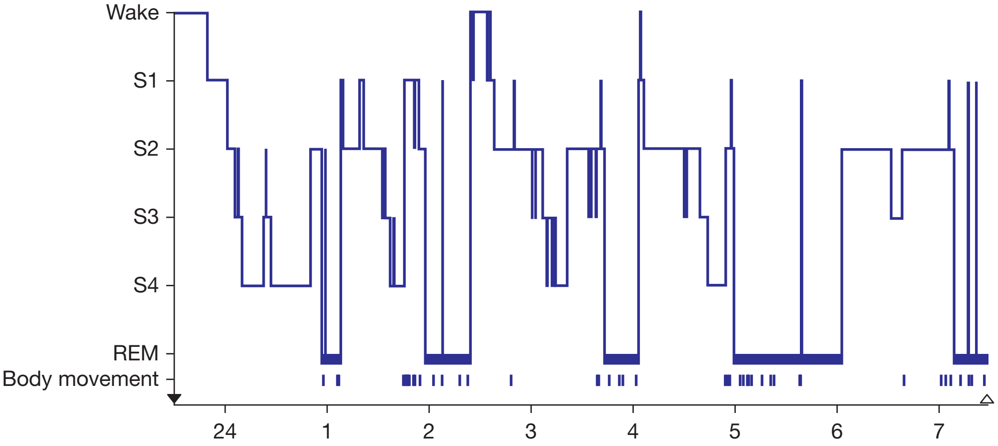

Figure 12-5 The progression of sleep stages across a single night's sleep of a normal young adult. The histogram was drawn on the basis of continuous recordings scored in 30-s epochs.

but recently stage 3 and stage 4 NREM sleep have been collapsed into one stage—N3. In this stage there is synchronized oscillatory firing of cortical neurons that generate large slow waves that are detected on the electroencephalogram (see Fig. 12-4). In all mammalian species there is distinct cycling of the different sleep stages, although the periods of these cycles vary between species. In humans the cycles have approximately a 90-minute duration, with episodes of REM sleep occurring every 90 minutes (Fig. 12-5). In the first part of the night individuals cycle down into stage 3 sleep; slow wave sleep occurs early in the sleep period. Episodes of REM sleep get longer and indeed more phasic, i.e., more eye movements etc., as the night progresses. Thus, typically humans are waking up out of REM sleep in the morning. There are major differences in the behavior of the cardiopulmonary system in these different sleep stages. These are discussed in Chapter 100.

MECHANISMS CONTROLLING SLEEP

Sleep is a circuit property. There is no evidence that single neurons sleep, although the intensity of "sleep" may vary across the brain—i.e., *local* sleep; slow waves in NREM sleep are particularly marked over brain regions that have been very active during wakefulness as a result of their involvement in specific tasks.[71,72] Much work over the last two to three decades has identified the neuronal basis for sleep/wake control.[69,73] Many neuronal groups have increased firing during wakefulness, reduced firing during NREM sleep, and virtually absent firing during REM sleep. These include the following: cholinergic cells in basal forebrain; orexin (hypocretin) cells in lateral hypothalamus; histamine cells in posterior hypothalamus; dopamine cells in peri-aqueductal grey; noradrenaline cells in locus coeruleus; and serotonin cells in brainstem raphe nuclei. While these neurons are all more active in waking, they are likely to have different functions during wakefulness. For example, it has been shown that orexin (hypocretin) neurons respond to emotions, e.g., positive emotions that result in pleasure increase the level of hypocretin.[74]

While all these neurons show similar differences in firing between wake and sleep states, there is a different pattern for cholinergic neurons in the pedunculopontine tegmentum (PPT) and lateral-dorsal tegmentum (LDT) in the brainstem. These neurons have reduced firing in NREM sleep compared with wakefulness but higher firing in REM sleep.[69] Thus, REM sleep is thought of as a time with higher cholinergic activity.[69]

While many neurons show increased firing during wakefulness, there is a more limited number of neurons that increase their activity during sleep. These neurons are in the ventro-lateral preoptic (VLPO)[75] and medial preoptic (MPO)[76] area of the hypothalamus. The VLPO has been called the sleep switch.[75] Neurons active during sleep contain the inhibitory neurotransmitter GABA and the neuropeptide galanin. Recently new neuronal groups that promote sleep have been identified such as GABA cells in the parafacial region.[77] Recent comprehensive reviews of the circuits controlling wake, NREM, and REM have been published.[78,79]

Since control of wake, sleep, and its stage is a circuit property, it has been proposed that behavioral state is controlled by a flip-flop[73] (Fig. 12-6). It is posited that wake-active neurons inhibit sleep-active cells during wakefulness but there are state-dependent changes such that a flip occurs and now sleep cells inhibit wake neurons during sleep. There is a secondary flip-flop that controls oscillation between NREM and REM sleep.[80]

In this proposed mechanism orexin cells play a critical role in stabilizing the flip-flop, i.e., preventing too many state transitions. Orexin cells play an important role in narcolepsy. Following the description of this new neuropeptide by two groups—one of which called the neuropeptide *hypocretin*[81] while the other called it *orexin*[82]—it was quickly recognized that it played a key role in narcolepsy. Dogs with a mendelian recessive genetic form of narcolepsy had mutations in the orexin-2 receptor that made it nonfunctional[83] while mice with orexin knockout showed key features of human narcolepsy.[84] Postmortem studies have shown that patients with narcolepsy and cataplexy have loss of orexin (hypocretin) neurons.[85] Thus, narcolepsy is likely to be an autoimmune disorder in which the main pathogenetic mechanism is destruction of orexin neurons.[86]

FUNCTIONS OF SLEEP

Although much effort has been made to understand the neuronal basis of sleep, an equally if not more important question is what the functions of sleep are. We spend about one-third of our lives sleeping. The question is what benefit do we obtain? Is the benefit just for the brain or do other organs, such as the lung, also obtain benefit?

While theories as to the functions of sleep have been proposed for decades, the concepts that have been articulated recently have in large part, although not exclusively, come from studies comparing gene expression (initially with microarrays; recently with RNA sequencing) between sleeping and awake animals (often enforced with sleep deprivation) sacrificed at the same time of day. The major focus, not surprisingly, has been on the functions of sleep for the brain. The proposed functions of sleep for the brain are discussed below.

■ Energy Restoration Hypothesis[87,88]

One of the concepts that has been proposed is the Benington-Heller hypothesis.[87] It posits that energy stores in brain—primarily glycogen in glia—are depleted during wakefulness and are restored during sleep. There are some data to support this.[89] However, the situation is more complex.[88] There is upregulation of key components of

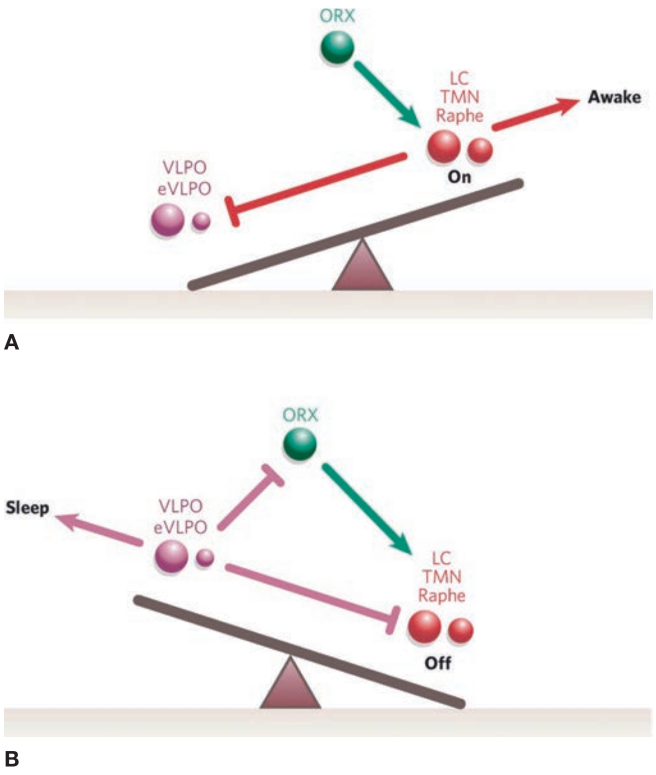

Figure 12-6 A schematic diagram of the flip-flop switch model. During wakefulness **(A)**, the monoaminergic nuclei inhibit the ventrolateral preoptic nucleus (VLPO), thereby relieving the inhibition of the monoaminergic cells, and that of the orexin (ORX) neurons, the cholinergic pedunculopontine (PPT), and the laterodorsal tegmental nuclei (LDT). Because the VLPO neurons do not have orexin receptors, the orexin neurons serve primarily to reinforce the monoaminergic tone, rather than directly inhibiting the VLPO on their own. During sleep **(B)**, the firing of the VLPO neurons inhibits the monoaminergic cell groups, thereby relieving their own inhibition. This also allows it to inhibit the orexin neurons, further preventing monoaminergic activation that might interrupt sleep. The direct mutual inhibition between the VLPO and the monoaminergic cell groups forms a classic flip-flop switch, which produces sharp transitions in state but is relatively unstable. The addition of the orexin neurons stabilizes the switch. eVLPO, extended ventrolateral preoptic nucleus.

the electron transport chain during wakefulness.[90] This is presumably to make ATP to provide increased energy resources during wakefulness with higher neuronal firing rates.

■ Synaptic Homeostasis Theory[91]

Expression of genes involved in synaptic upscaling such as BDNF and ARC are upregulated during wakefulness and downregulated during sleep.[92] This has led to the concept that there is synaptic upscaling during wakefulness and downscaling during sleep.[91] There are data to support this hypothesis. In *Drosophila* there are increased amounts of synaptic proteins detected during wakefulness and less during sleep.[93]

There is, however, contradictory evidence. In developing animals there is evidence that synaptic plasticity is enhanced during sleep (not wakefulness).[94] It is conceivable, of course, that this phenomenon is specific to the developmental period. Sleep is a critical period for brain development.[95] It is also conceivable that changes in synaptic plasticity with sleep/wake are different in different brain regions.[96] Thus, much remains to be determined and it is likely that the situation is more complex than simply strengthening of synapses during wakefulness and downscaling during sleep.

■ Macromolecular Biosynthesis[97]

Microarray studies also suggest that sleep is a stage of macromolecular biosynthesis. Among classes of genes whose expression is increased in cerebral cortex and hypothalamus during sleep compared with wakefulness are genes involved in macromolecular biosynthesis.[98] These gene classes are very overrepresented among genes whose expression is increased during sleep.[98] This involves pathways for multiple molecules, e.g., all genes in the cholesterol synthesis pathway, six of seven genes in heme synthesis pathway, and genes involved in protein synthesis. Thus, sleep and wake may be part of a metabolic cycle.[99] Energy resources during wakefulness are used for neural activity, e.g., ion pumps, but during sleep they are used for macromolecular biosynthesis. Thus, sleep is a stage where new molecules are made to restore membranes, vesicles, etc., i.e., to prepare for subsequent wakefulness.

■ Oxidative Stress and DNA Repair[100]

As described above, there is upregulation of the various components of the electron transport chain during wakefulness.[90] This will result in increased production not only of ATP but also free radicals. During sleep there is upregulation of expression of antioxidant enzymes in different brain regions.[98] Studies in *Drosophila* find a bidirectional relationship between sleep and oxidative stress.[101] Specifically, overexpression of genes for antioxidant enzymes in neurons reduces the amount of sleep.[101] There are data indicating that an oxidative byproduct regulates the electrical activity of key neurons in *Drosophila* that respond to sleep need.[102] Thus, the "flip" from wake to sleep may in part be determined by oxidative changes.

Increased free radicals also lead to DNA damage.[103] There is evidence that DNA repair mechanisms are upregulated during sleep[100,104] (Fig. 12-7). Studies in zebrafish show reduction in double-strand DNA breaks during sleep.[105] Moreover, in zebrafish administration of a molecule that leads to double-strand breaks increased sleep.[105] Thus, the need for sleep may be coupled to the amount of DNA damage that accumulates during wakefulness. Upregulation of expression of DNA repair genes during sleep is attenuated in older mice compared with young,[106] i.e., the molecular functions of sleep are attenuated with age.

■ Recovery from ER Stress[107]

Another concept that arose from microarray studies is that prolonged wakefulness leads to endoplasmic reticulum (ER) stress with protein misfolding.[107,108] This was suggested by the observation that the molecular chaperone, BiP, the master regulator of the unfolded protein response,[109,110] is upregulated in multiple brain regions in multiple species with sleep loss.[107,108] The unfolded protein response is a ubiquitous protective mechanism that is activated when stress occurs in the ER with misfolding of proteins.[109,110] The UPR results in helping misfolded proteins to fold properly, chaperoning those not folded out for degradation and inhibition of protein translation to reduce protein production.[109,110] All components of the unfolded protein response are activated in mouse cerebral cortex following 6 hours of sleep loss.[111] Inhibiting protein translation by administration of the drug salubrinal, a modulator of the ER stress response, enhances slow wave sleep and activates sleep promoting neurons in the medial pre-optic area.[112]

■ Clearance of Compounds from Brain[113]

The brain is unique among organs in that it has a limited lymphatic system. Thus the question: How are compounds cleared from the

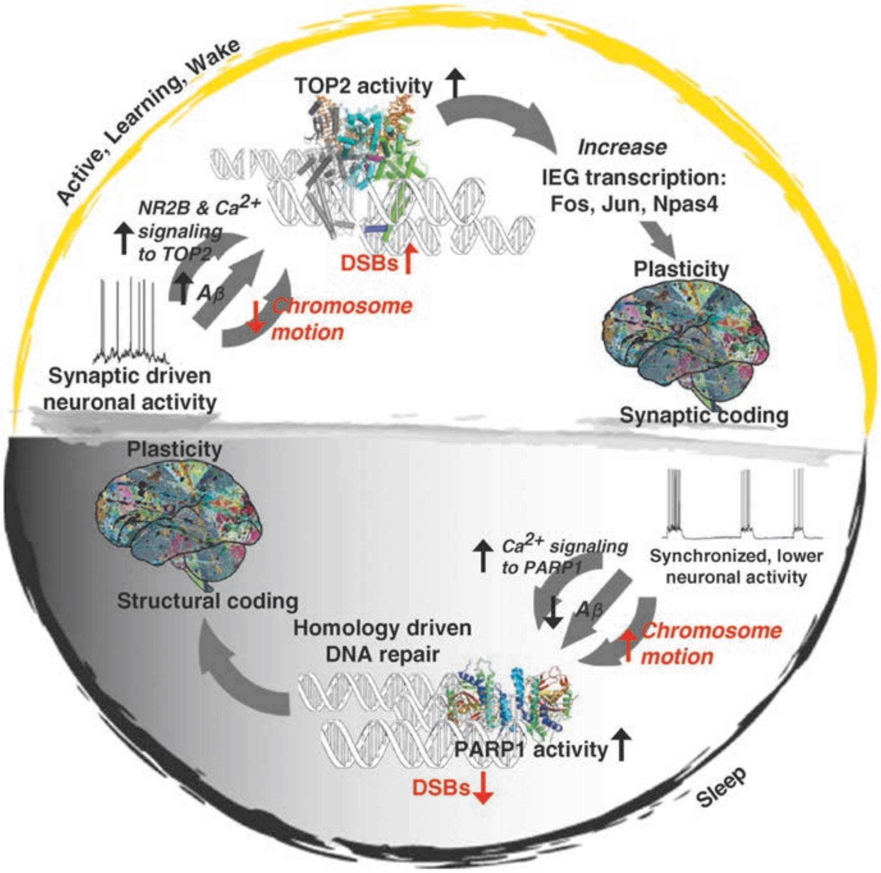

Figure 12-7 Sleep and DNA repair. There are increasing DNA double-strand breaks during wakefulness. DNA repair occurs during sleep. *(Reproduced with permission from Mourrain P, Wang GX. Sleep: DNA Repair Function for Better Neuronal Aging? Curr Biol. 2019;29(12):R585–R588.)*

brain? This has led to the intriguing concept of glia-lymph, i.e., glial cells in brain are responsible for clearance of compounds. Compounds are much more rapidly cleared during sleep than during wakefulness.[113] Studies with fluorescent-labeled compounds show that there is substantially more convective flux across the brain in sleeping compared with waking animals.[113] The precise mechanism that allows this increased transport to occur during sleep is unknown, although it seems to be a result of lower levels of the neurotransmitter noradrenaline during sleep.[113] A compound that is cleared more rapidly during sleep is beta-amyloid, which plays a key role in the pathogenesis of Alzheimer's disease. Thus, disturbances of sleep might accelerate Alzheimer's pathology. This has been shown experimentally in mice since sleep loss over many days accelerates plaque development in a mouse model of the disease.[114] Moreover, sleep apnea is now recognized as an independent risk factor for mild cognitive impairment and dementia.[115]

■ Memory Consolidation[116,117]

All the above indicates that at a molecular level sleep is an active state with several specific functions. It is not only an active state at a molecular level but also with respect to cognition and memory consolidation. Performance or tasks that require identification of a "hidden rule" are enhanced following sleep, i.e., sleep allows the brain to continue to process information and enhances insight.[118] Memory tasks are enhanced after sleep. This is not simply a matter of time since repeating the task several hours later during wakefulness does not result in this enhancement. Enhancement of performance in some tasks is correlated with the amount of slow-wave sleep while for other tasks the correlation is with the amount of REM sleep.[116,117] It has been proposed that REM sleep enhances procedural and emotional memories, while slow wave sleep enhances declarative memories.[117] Sleep enhancement of memory is reduced with aging.[119]

Thus, sleep seems to have many functions for brain rather than simply one. This is not surprising since it seems logical to ensure maximal benefit from "downtime." The discussion of functions of sleep largely treats sleep as a single entity. We know, however, as described above, that there are specific stages of sleep. Thus, it is conceivable that slow-wave sleep and REM sleep have different functions (see discussion above about memory consolidation). One of the challenges to elucidating function of different stages of sleep is that in mouse models REM sleep episodes are extremely short—on the order of minutes. They are so short that if REM sleep has particular functions, they cannot be at the transcriptional level but are likely to be related to post-translational modifications. It is of interest to consider what the impact of fragmented sleep, such as occurs in obstructive sleep apnea (see Chapter 99), will have on the functions described. This has not, however, been studied and is an area of research need and opportunity.

DOES THE LUNG SLEEP?

One of the fundamental tenants of sleep biology is that sleep is by the brain and for the brain—a title of a provocative article in *Nature*.[120]

Again, data from studies of gene expression challenge this tenet. Comparing gene expression between sleeping and awake animals sacrificed at the same time of day shows that there are common pathways downregulated in both lung and heart during sleep. As in brain, these pathways are those involved in ER stress, molecular chaperones, and heat shock molecules.[121] There is remarkable similarity in the changes in gene expression in both organs with sleep and sleep deprivation in key genes in these pathways (Fig. 12-8). This suggests that there must be a common signaling mechanism that leads to these dynamic changes in expression of these genes in different tissues in a coordinated way. The nature of this mechanism is unknown. While there

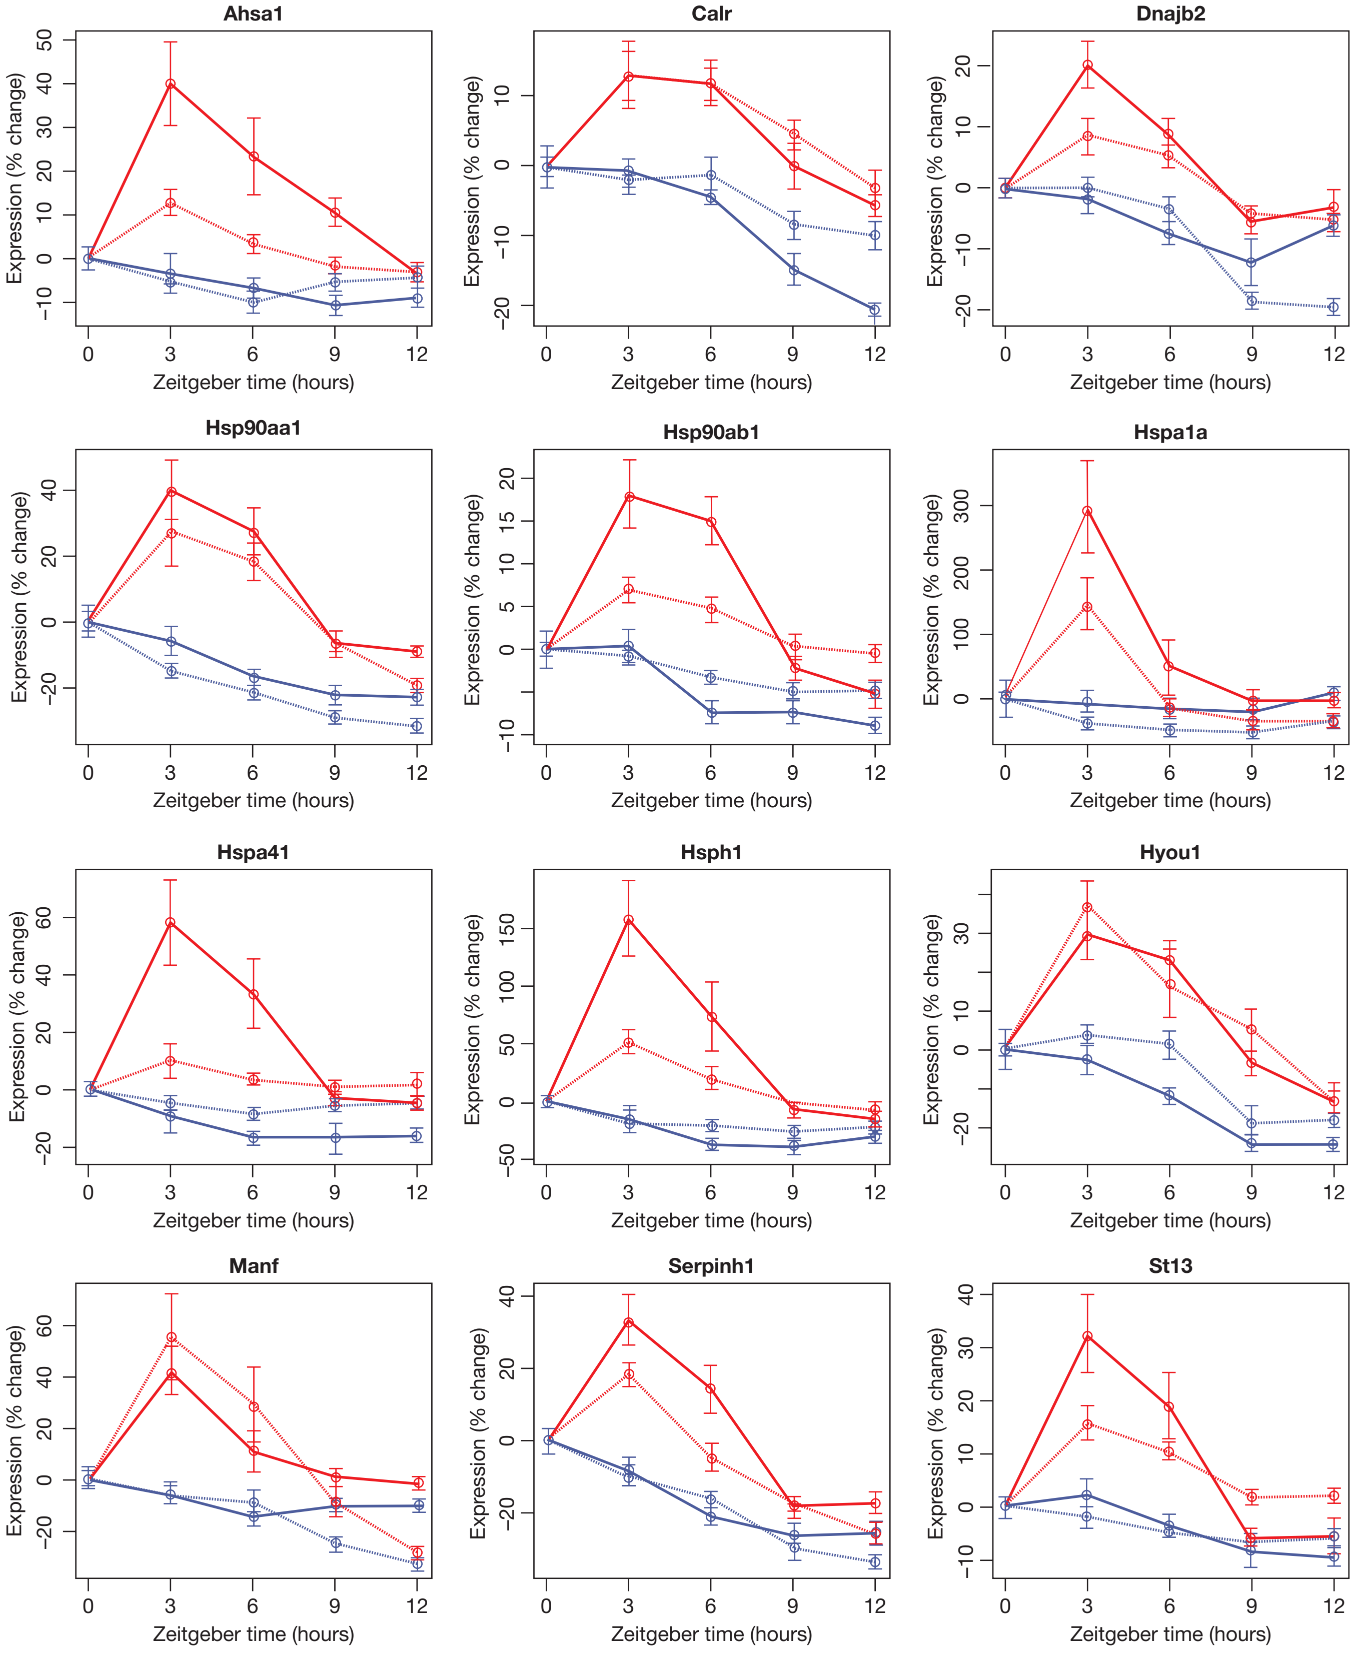

Figure 12-8 Transcript profiles of sleep-repressed genes involved in the unfolded protein response. Temporal profiles of expression for select sleep-responsive genes with annotations relating to protein processing and endoplasmic reticulum (ER) stress. Changes in gene expression from the baseline condition (lights on) are plotted as a percent of baseline expression levels. Maroon curves show data from experimentally sleep-deprived animals, and blue curves show data from spontaneously sleeping animals. Data from heart tissue are connected with dashed lines. Data from lung tissue are connected by uninterrupted lines. All genes shown here met statistical criteria for sleep specific repression in both tissues. Data shown represent mean ± standard error for 8 or 9 biological replicates. *(Reproduced with permission from Anafi RC, Pellegrino R, Shockley KR, et al. Sleep is not just for the brain: transcriptional responses to sleep in peripheral tissues. BMC Genomics. 2013;362.)*

AL GRAWANY

are common gene pathways downregulated in sleep in lung and heart, upregulated pathways with sleep are different between organs. In the lung there is upregulation of certain genes for antioxidant enzymes. Thus, is sleep a time for clearing the free radicals produced in the lung during the day? This is similar to the concept described above for brain. There is a need for more in-depth exploration of the changes in the lung during sleep. These recent data would lead to the conclusion, however, that the lung does indeed sleep.

CONCLUSION

Sleep and circadian biology are dynamic areas of research. New concepts are emerging, and some of the fundamental mechanisms are being elucidated. From the point of view of the pulmonologist, there are two major issues. First, both circadian rhythm and sleep have direct effects on molecular mechanisms in the lung. Second, disturbances of sleep like those produced by sleep-disordered breathing or jet lag will have adverse consequences at a molecular level on the functions of sleep, including in the lung itself.

CHAPTER 13

The Pulmonary Circulation

Robert Naeije

INTRODUCTION

The discovery of the pulmonary circulation was reported in the 13th century by Ibn al-Nafis (1213–1288) in the "Commentary on Anatomy in Avicenna's Canon" and, probably independently, in the 16th century by Michael Servetus (1511–1553) in the "The Restoration of Christianity."[1] The pulmonary circulation as a separate high-flow low-pressure system is the end result of an evolutionary process aimed at the optimization of gas exchange of endothermic birds and mammals.[2] Evolution from ancestors of fishes to amphibians, reptiles, and finally birds and mammals has led to progressively greater oxygen consumption requiring thinner pulmonary blood gas barrier. The alveolo-capillary membrane in mammals is a vulnerable structure only 0.3 μm thick. Preservation of the integrity of this barrier requires complete separation of the pulmonary circulation from the systemic circulatory systems, which is accompanied by a progressive unloading and reshaping of the right ventricle as a thin-walled flow generator.

The extreme possible physiologic stresses on the pulmonary circulation are exercise and hypoxia. Exercise increases oxygen uptake and carbon dioxide output up to some 20-fold above resting values and increases cardiac output up to some 6-fold. Strenuous exercise may eventually alter gas exchange because of excessive capillary filtration and stress failure, or expose the right ventricle to excessive loading resulting in a limitation of maximum cardiac output. Hypoxia adds the burden of further increase in pulmonary vascular pressures due to hypoxic pulmonary vasoconstriction.

PULMONARY VASCULAR PRESSURES AND RESISTANCE

Pulmonary blood flow is determined by the driving pressure in the pulmonary circulation and resistance to flow, as discussed below.

■ Normal Relationships

Pulmonary blood flow (CO) is driven by a pressure difference between an inflow pressure, or mean pulmonary artery pressure (mPAP), and an outflow pressure, or mean left atrial pressure (LAP). From these measurements, resistance to flow in the pulmonary circulation can be approximated by a single number, pulmonary vascular resistance (PVR), which depends on the ratio between (mPAP − LAP) and CO:

$$\text{PVR} = (\text{mPAP} - \text{LAP})/\text{CO}$$

In clinical practice, measurements of pulmonary vascular pressures and pulmonary blood flow are performed during a catheterization of the right heart with triple-lumen, fluid-filled balloon- and thermistor-tipped catheter technology introduced by Swan, Ganz, and Forrester in the 1970s.[3,4]

As illustrated in Fig. 13-1, the procedure allows for the estimation of LAP from a balloon-occluded or wedged PAP (PAOP or PAWP). Wedged or occluded PAP are usually grouped under the term PAWP, as a discrepancy may occur only in case of an increase in large pulmonary vein resistance, which is very rare. The fractal structure of the pulmonary arterial and venous trees allows for a stop-flow phenomenon downstream of occlusion and de facto extension of the fluid-filled lumen of the catheter to same diameter pulmonary veins. A left heart catheterization allows for the measurement of left ventricular (LV) end-diastolic pressure (EDP) to estimate LAP in the absence of mitral stenosis. With injection of 5 to 10 mL cooled saline into a lumen opening into the right atrium, a temperature change over time in the pulmonary artery is registered and CO is calculated from the thermal dilution curve. Cardiac output can also be calculated by the so-called "direct Fick method" or ratio between oxygen uptake ($\dot{V}O_2$) and the arterio-mixed venous oxygen content difference ($CaO_2 - C\dot{v}O_2$).

$$\text{CO} = \dot{V}O_2/(CaO_2 - C\dot{v}O_2)$$

But this also requires systemic arterial blood sampling, measurements of inspired and expired oxygen concentrations, and a steady state, which is sometimes difficult to attain.[5]

■ Methodologic Aspects

Fluid-filled thermodilution catheter measurements of pulmonary vascular pressures and CO are accurate (i.e., no bias by Bland and Altman analysis), but may suffer from an inherent lack of precision (i.e., large limits of agreement by Bland and Altman analysis).[6] Errors in the measurements of PAP with fluid-filled catheters compared with gold standard, high-fidelity micromanometer-tipped catheters range from −8 to +8 mm Hg.[7] Errors in the measurement of thermodilution CO when compared with the gold standard direct Fick method range from −1 to +1 L/min.[8] Reported errors in the estimation of LVEDP from PAWP in large series of patients range from −15 to +12 mm Hg.[9,10] Accurate but imprecise measurements are suitable for population studies, but they are to be used cautiously for individual decision-making.[6]

Fluid-filled catheters measure vascular pressures with an external manometer, which requires zero levelling. For this purpose, the best reference is at the cross-section of three trans-thoracic planes: mid-chest frontal, transverse through the fourth intercostal space, and sagittal.[11] This is close to the hydrostatic indifference point, located at the tricuspid valve, where pressure is independent of body position.[12]

Pulmonary vascular function is affected by changes in lung volumes and in intrathoracic pressures. PVR is minimal at functional residual capacity (FRC). Lung volumes below or above FRC are associated with increased PVR, because of predominant increased in alveolar vessel resistance at high lung volumes and increased extra-alveolar vessel resistance at lower lung volumes.[13] Pleural pressure is slightly subatmospheric, on average, at −3 mm Hg at FRC. Pleural pressure decreases at inspiration and increases at expiration. Pulmonary vascular pressures, systolic and diastolic right heart pressures, and diastolic, but not systolic, left heart pressures follow the changes in pleural pressure.[14] Expiration may be associated with dynamic hyperinflation, increased FRC, and positive alveolar pressures, which are transmitted to pleural pressure. Respiratory swings of pulmonary vascular pressures are illustrated in Fig. 13-2. During normal breathing, pulmonary vascular pressures are, therefore, best averaged over several respiratory cycles.[15]

Adequate measurement of a PAWP requires attention to wave morphology. For the estimation of LAP or LVEDP, which are identical in diastole, reading the tracing at the nadir preceding the c wave, or using a QRS-gated approach (130–160 ms after the Q) and omitting of course the V wave, which is systolic, is recommended.[15] However, for the estimation of the outflow pressure of the pulmonary circulation and calculation of PVR, it is preferable to average the reading

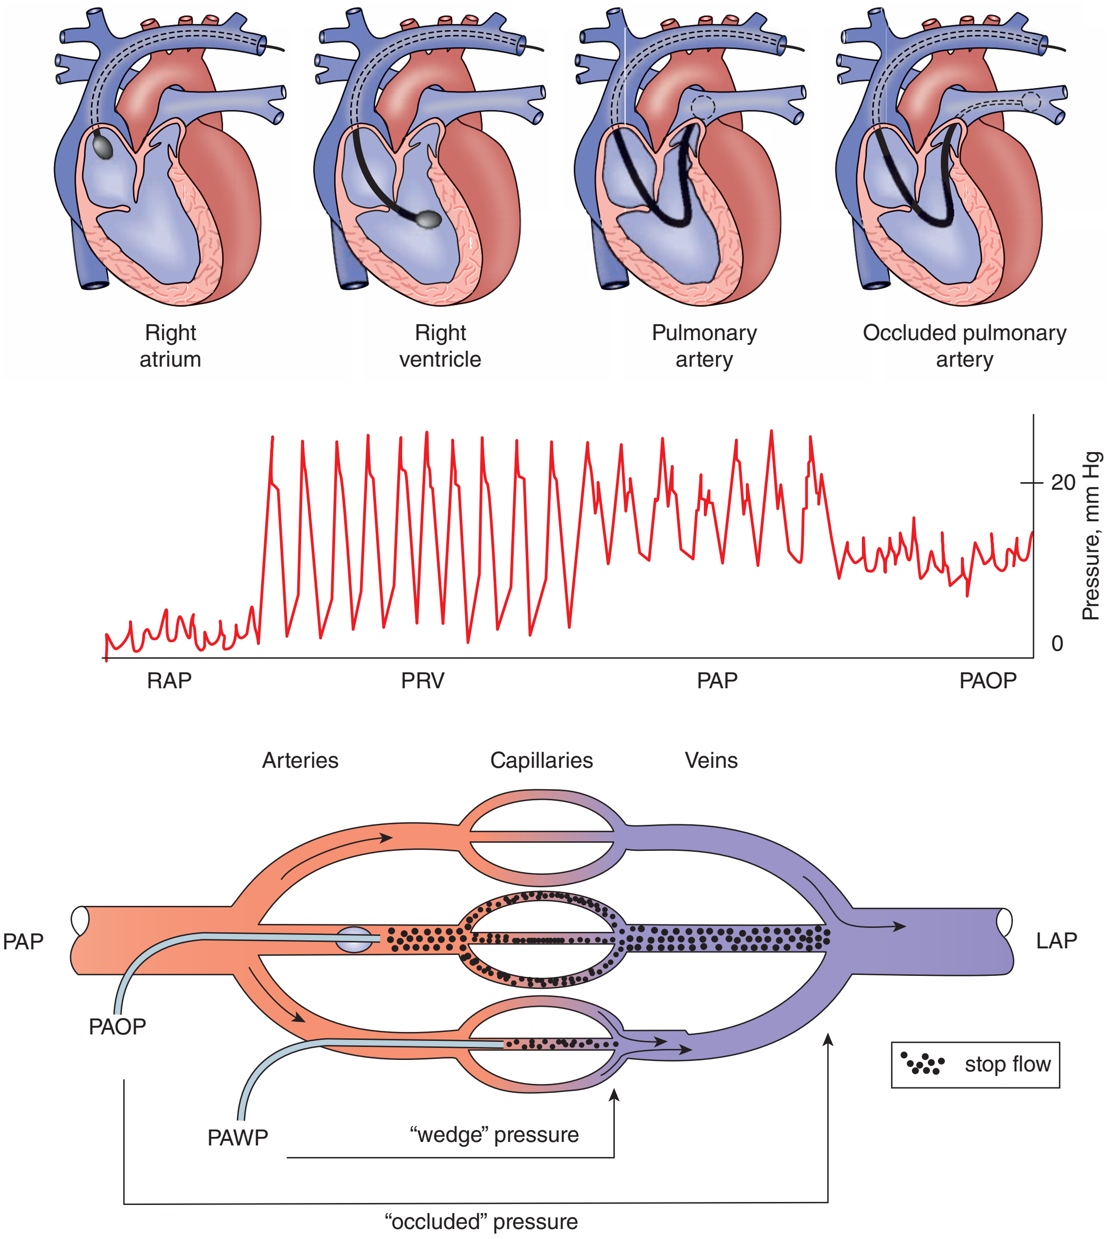

Figure 13-1 Right heart catherization with flow-directed balloon-tipped catheter with successive measurements of right atrial pressure (RAP), right ventricular pressure (PRV), pulmonary artery pressure (PAP), and occluded PAP (PAOP). Because of the fractal structure of the arterial and venous branching of the pulmonary vascular tree, occluded or wedged PAP (PAWP) prolongs the fluid column of the catheter until same diameter pulmonary vein, which is a satisfactory estimate of left atrial pressure (LAP) or left ventricular end-diastolic pressure.

of a PAWP tracing over the cardiac cycle, as the V wave pressure is transmitted upstream to PAP. Omission of the V wave could markedly overestimate PVR. Reading a PAWP, while taking into account cardiac cycle and respiratory cycle variability, is illustrated in Fig. 13-2.

Sometimes a measurement of LVEDP or PAWP cannot be obtained, and a *total* PVR (TPVR) is calculated as:

$$\text{TPVR} = \text{mPAP/CO}$$

Since LAP is not negligible with respect to mPAP, TPVR is larger than PVR, and this difference may be flow-dependent. Thus, TPVR is not a correct characterization of the flow-resistive properties of the pulmonary circulation when LAP is increased. On the other hand, TPVR may be a more realistic estimate of right ventricular (RV) afterload. The RV is exposed to PAP, and not to the difference between PAP and LAP.

■ Pulmonary Capillary Pressure

While wedged or occluded PAP measurements are acceptable estimates of LAP, micropuncture studies have shown that pulmonary capillary pressure (PCP) is higher than PAWP, lying about halfway between arterial and venous pressures.[16] Thus, wedged or occluded PAP should not be called "capillary" or "capillary-wedge" pressure. Estimates of PCP can be obtained from the analysis of PAP decay curves after arterial occlusion (Fig. 13-3).[17]

Pulmonary artery pressure decay curves present with a first rapid portion, corresponding to the interruption of flow through arterial resistance, and then a slow capillary-venous portion corresponding to the emptying of pulmonary capillary compliance through venous resistance. The inflection point of the pressure decay curve defines PCP.[17]

Based on measured distribution of resistances in perfused normal lungs, assuming 60% arterial resistance and 40% capillary plus

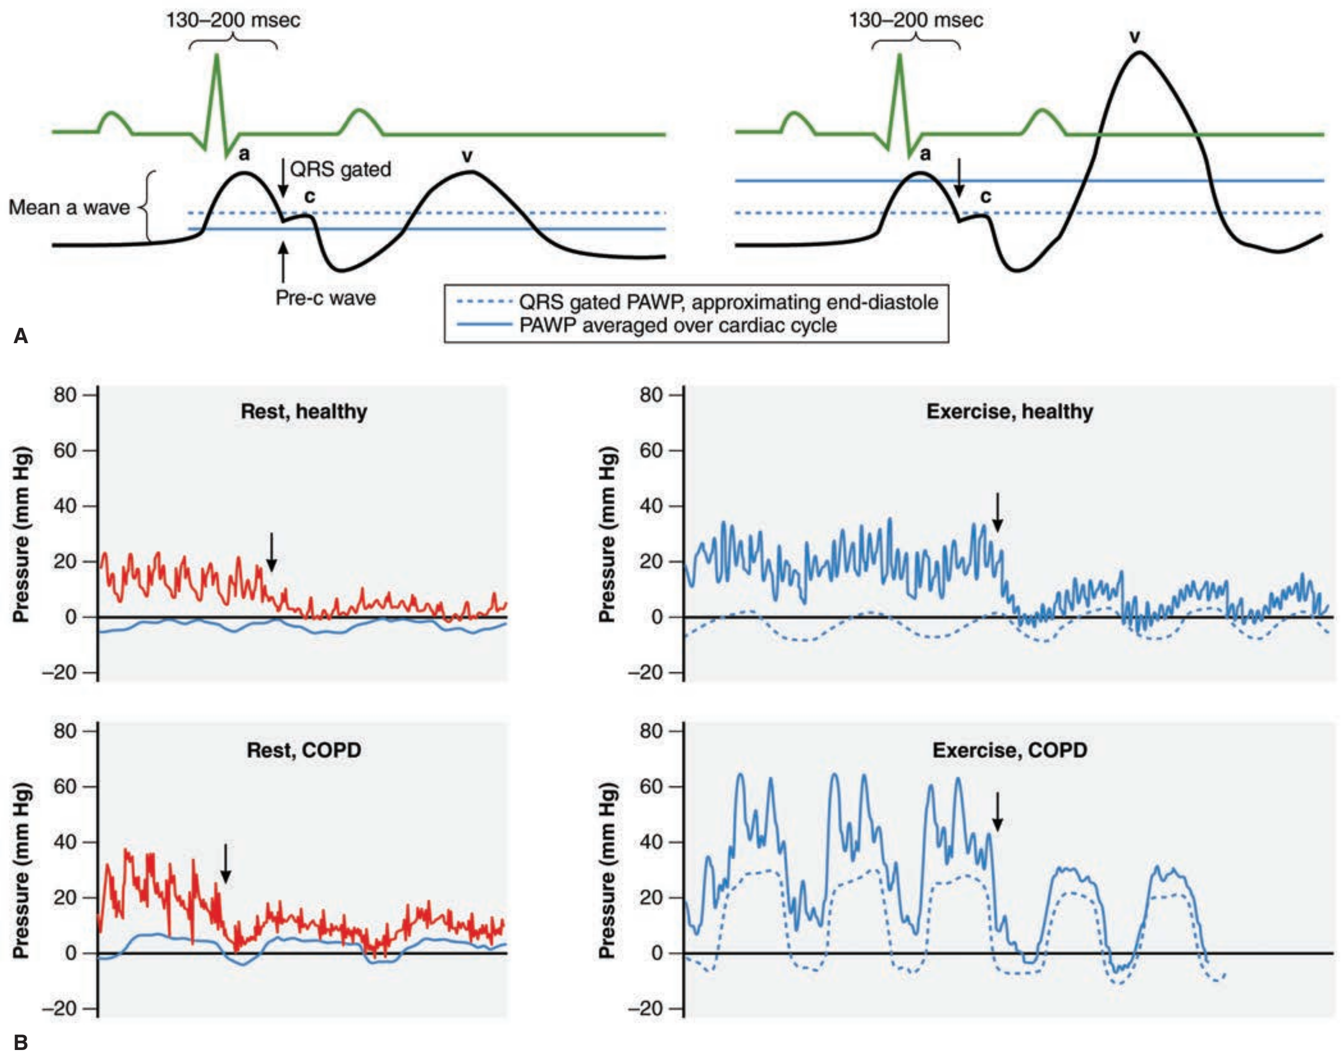

Figure 13-2 Impact on respiratory and cardiac cycle timing on pulmonary artery wedge pressure (PAWP). **A.** Pulmonary arterial wedge pressure tracing. Measurements that approximate end-diastole (mean a wave, pre-c wave, and QRS gated assessment at 130–160 ms from the onset of QRS to allow time delay between PAWP and left atrial pressure, shown in gray) should provide the closest approximation of left ventricular end-diastolic pressure (LVEDP). This value is usually slightly higher than the PAWP averaged over the cardiac cycle (solid line). However, the reverse occurs in the setting of a large V wave (right panel). **B.** Pulmonary arterial pressure and wedge pressure tracing at rest (red) and with exercise (blue), with pleural pressures shown below (dashed lines). Pulmonary vascular pressure changes follow pleural pressure changes, which are more pronounced in chronic obstructive pulmonary disease (COPD). *(Reproduced with permission from Naeije R, Chin K. Differentiating Precapillary From Postcapillary Pulmonary Hypertension. Circulation. 2019;140(9):712–714.)*

venous resistance, PCP can be estimated from a simple equation proposed by Gaar et al.:[19]

$$\text{PCP} = \text{PAWP} + 0.4 \times (\text{mPAP} - \text{PAWP})$$

Measurements of PCP by single PA occlusion in healthy volunteers show an average PCP of 10, ranging from 8 to 12 mm Hg.[18]

■ Limits of Normal

The limits of normal of the human pulmonary circulation derived from invasive measurements reported in 47 studies on a total of 1187 individuals, of whom 225 were identified as women and 717 as men,[20] are shown in Table 13-1.

■ Calculation of PVR

A vascular resistance calculation derives from the physical law that governs laminar flows of Newtonian fluids through nondistensible, straight cylindric tubes, originally proposed by the French physician Poiseuille and later put in mathematical equation by the German physicist Hagen. Poiseuille showed experimentally that flow was inversely related to the fourth power of the internal radius, and he confirmed previous demonstrations that arterial pressure remains high in arteries down to 2 mm in diameter, while venous pressure is low in animals. The Hagen-Poiseuille law states that resistance, R, to flow of a single tube is equal to the product of the length, l, of the tube and viscosity, η, and a constant, 8, divided by the product of π and the fourth power of the internal radius, r. More generally, R can be calculated as the ratio of pressure drop, ΔP, to flow, Q:

$$R = l \bullet \eta 8/\pi \bullet r^4 = \Delta P/Q$$

The ratio of pressure drops to flow through an entire vascular bed accounts for the resistances in series and in parallel of the individual vessels. The fact that r in the equation is to the fourth power explains why R is exquisitely sensitive to small changes in caliber of these small vessels (e.g., a 10% change in radius results in an almost

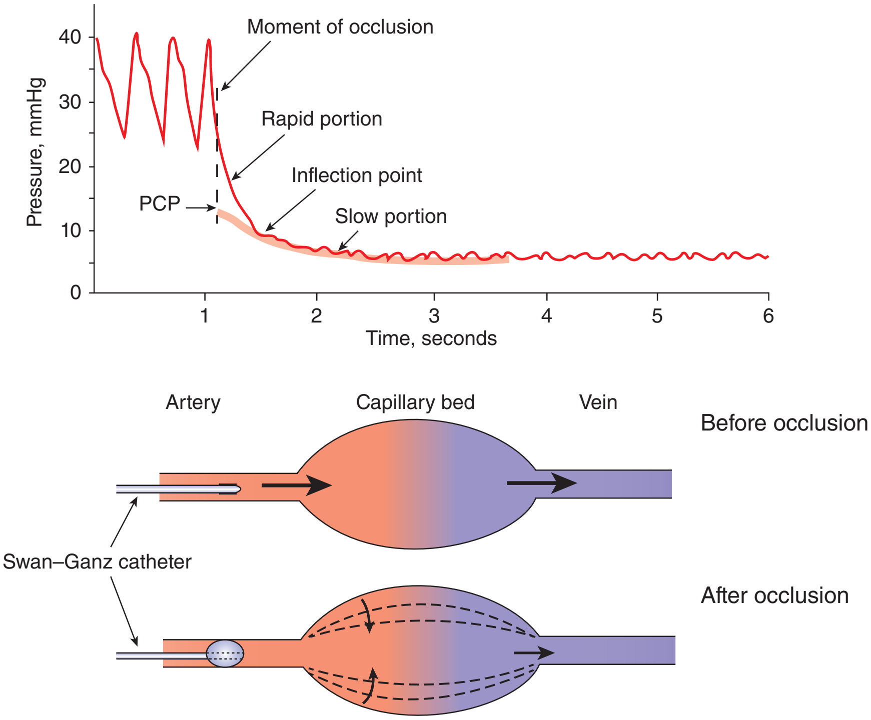

Figure 13-3 Analysis of the pressure transient after pulmonary arterial occlusion for the estimation of pulmonary capillary pressure (PCP) either by the intersection of the fast and the slow components of the pressure decay curve, or by the extrapolation of the exponential fitting of the slow component of the pressure decay curve to the moment of occlusion.

50% change in resistance). Accordingly, PVR is a good indicator of the state of constriction or dilatation of pulmonary resistive vessels and is useful for detecting changes in arteriolar vessel caliber due to changes in tone or structure.

■ Effects of Age, Sex, and Body Position

Generally, women are of smaller body size than men. Accordingly, cardiac output is lower and PVR higher in women.[20] However, there are no sex differences in pulmonary hemodynamics after correction for body dimensions. Aging is associated with an increase in PVR. This is due to a slight increase in mPAP and a more important decrease in cardiac output, leading to a doubling of PVR over five decades of life.[21,22] However, measurements in healthy old individuals are few; hence, the exact limits of normal of the pulmonary circulation as a function of age are not exactly known.

Body position affects PVR through associated changes in systemic venous return. In the upright position, LAP, right atrial pressure (RAP), and CO are lower than in the supine position. This results in a de-recruitment of pulmonary vessels, and mPAP remains essentially the same. Accordingly, PVR is increased at rest in the upright position.[23,24] When cardiac output is increased during an incremental exercise test, body position does not affect the slope of pulmonary vascular pressure-flow relationships.[23,24] The effects of body position on PVR at rest and during exercise, as in reported data from 96 healthy subjects,[25] is illustrated in Fig. 13-4.

TABLE 13-1 Limits of Normal of Pulmonary Vascular Pressures and Pulmonary Blood Flow at Rest

Variables	Mean	Limits of Normal
CO, L/min	7.3	5.0–9.5
HR, bpm	76	50–100
PAP systolic, mm Hg	21	13–29
PAP diastolic, mm Hg	9	3–15
PAP, mean, mm Hg	14	8–20
PAWP, mm Hg	8	2–14
PCP, mm Hg	10	8–12
RAP, mm Hg	5	1–8
PVR, Wood units	0.9	0.2–1.8

■ Limits of Normal and Definition of Pulmonary Hypertension

Currently expert consensus defines pulmonary hypertension (PH) as a mPAP >20 mm Hg, precapillary PH as a mPAP >20 mm Hg with PAWP ≤15 mm Hg and PVR ≥3 Wood units (WU), and postcapillary PH as a mPAP >20 mm Hg with PAWP >15 mm Hg and PVR <3 WU.[26] Data from large population registries show that a mPAP >20 mm Hg and a PVR >2 WU are independently associated with a decreased life expectancy.[27,28] A PVR at the upper limit of normal of 2 WU can be modeled to correspond to 20%–25% obstruction of the pulmonary circulation at a normal cardiac output.[29]

■ Effects of Pulmonary Blood Flow

The inherent assumption in a PVR calculation is that the mPAP-flow relationship is constant and crosses the pressure axis at a value equal to LAP (such that when flow is zero, theoretically, mPAP =

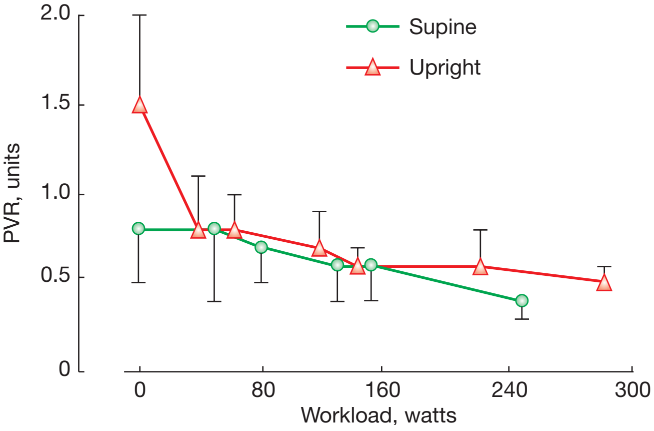

Figure 13-4 Pulmonary vascular resistance (PVR) at rest and during progressively increased workload in healthy volunteers in the upright (triangles) vs. the supine position (circles). Resting PVR was higher in the upright position. As soon as at moderate workload, upright and supine PVR converge, with mild further decline with increasing levels of exercise. Vertical bars indicate SDs. *(Data from Weir EK, Reeves JT: Pulmonary Vascular Physiology and Physiopathology. New York, NY: Marcel Dekker; 1989.)*

LAP). Then, PVR is constant, independent of the absolute pressure or flow.

The relationship between (mPAP − LAP) and CO has been shown to be reasonably well described by a linear approximation over a limited "physiologic" range of flows, with a zero extrapolated pressure intercept in well-oxygenated lungs in supine resting intact animals, including humans, suggesting complete recruitment and minimal distension of the normal well-oxygenated pulmonary circulation. However, hypoxia and a number of cardiac and respiratory diseases increase both the slope and the extrapolated intercepts of multipoint mPAP-CO.[30]

While an increase in the slope of mPAP-Q is easily understood as being caused by a decreased cross-sectional area of pulmonary resistive vessels, the non-zero and, typically, positive extrapolated pressure intercept has inspired various explanatory models.

■ The Starling Resistor Model of the Pulmonary Circulation

To explain the non-zero and positive pressure intercept, Permutt et al. conceived a vascular "waterfall" or "Starling resistor" model made of parallel collapsible vessels with a distribution of non-zero and positive closing pressures.[31] The waterfall analogy refers to the fact that the flow rate (CO) over a waterfall is independent of its height (the pressure difference between upstream and downstream). Instead, an "external" factor (in the case of a waterfall, fluid momentum) controls the flow rate. The Starling resistor itself was actually a device: a collapsible tube inside of a closed chamber that could be pressurized, thus providing an "external" control over the flow rate through the collapsible tube. Starling used this device in the circuit of his heart-lung preparation to control blood pressure.

Permutt et al. postulated that in the pulmonary circulation, as flow decreased, arteries would be progressively de-recruited, accounting for a low-flow mPAP-CO curve that is concave to the flow axis and intercepts the pressure axis at the lowest closing pressure needed to be overcome to generate a flow. At higher flows, complete vessel recruitment and negligible distension account for a linear mPAP-CO curve, with an extrapolated pressure intercept representing a weighted mean of closing pressures. In this model, the mean closing pressure is the effective outflow pressure of the pulmonary circulation. At higher flows, LAP is equal to the mean closing pressure. However, at lower flows, LAP is less than the mean closing pressure and becomes irrelevant to flow, analogous to the height of water below a waterfall (Fig. 13-5).

A characteristic typical of a vascular system made up of collapsible vessels is the functional dissociation between inflow, outflow pressures, and flow rate when the closing pressure is higher than the (apparent) outflow pressure (Fig. 13-6).

The functional dissociation of inflow and outflow outflow pressures is a feature of de-recruited upright upper lung zone I described by West.[32] It has been reported in pulmonary hypertension on acute lung injury[33,34] and in occasional cases of pulmonary hypertension on terminal heart failure, after cardiac transplantation.[35] An increased closing pressure possibly explains positive extrapolated pressure intercepts on mPAP-CO plots in idiopathic pulmonary arterial hypertension (PAH).[36,37] However, experimental data have been accumulated that cannot be explained by the Starling resistor model of the pulmonary circulation in embolic pulmonary hypertension[29,38,39] or increased hematocrit,[40] and the assumption that recruited vessels are not distensible is not correct.[41] Therefore, distensibility models at variable hematocrit have been developed.

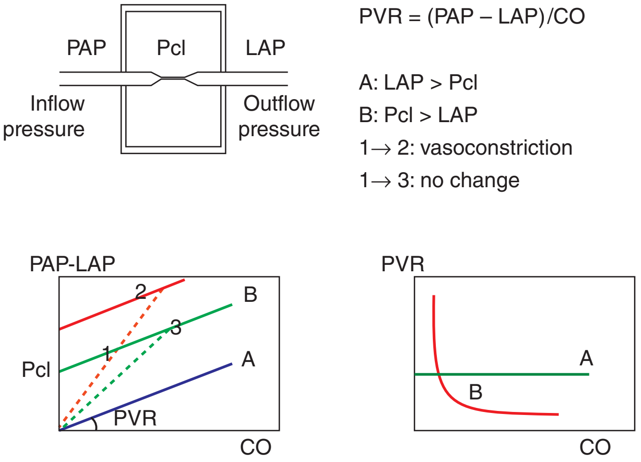

Figure 13-5 Starling resistor model of the pulmonary circulation as a collapsible tube within a pressure chamber. Pulmonary artery pressure (PAP) is the inflow pressure, left atrial pressure (LAP) is the apparent outflow pressure, and the pressure in the chamber Pcl is a closing pressure. Pulmonary vascular resistance (PVR) is a pressure difference vs. flow (CO) relationship, with either PAP – Pcl or PAP – LAP as a driving pressure depending on whether Pcl is greater than LAP. The pressure difference vs. flow relationship is linear. Low-flow convexity to the pressure axis is explained by vascular recruitment. When Pcl > LAP, PVR decreases when flow increases. *(Reproduced with permission from Naeije R. Pulmonary vascular resistance. A meaningless variable? Intensive Care Med. 2003;29(4):526–529.)*

■ Distensible Models of the Pulmonary Circulation

Zhuang modeled the feline pulmonary circulation, taking into account not only morphometry but also mechanics (i.e., distensibility) of the pulmonary vascular tree and rheologic properties of each of its branched segments.[42] The authors predicted mPAP-CO curves with a slight curvilinearity concave to the flow axis over physiologic ranges

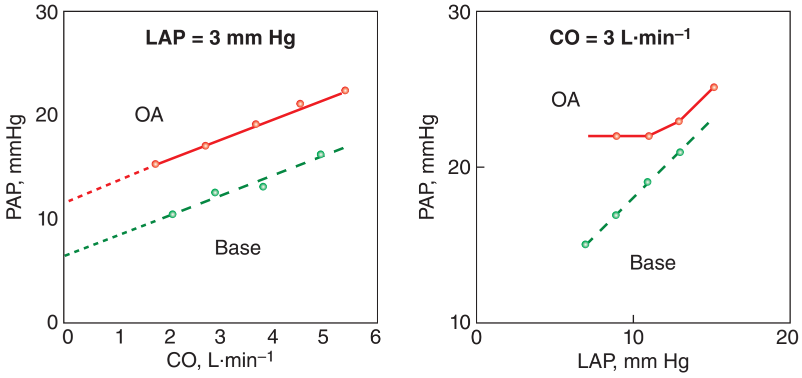

Figure 13-6 Mean pulmonary artery pressure (mPAP) vs. cardiac output (CO) at constant left atrial pressure (LAP) (left panel), and mPAP vs. LAP at constant CO (right panel) before and after induction of oleic acid (OA) lung injury in an anesthetized dog. Oleic lung shifts the linear mPAP-CO relationship in parallel to higher pressure, with an extrapolated pressure intercept higher than LAP, suggesting an increased closing pressure, which is confirmed by a functional dissociation between mPAP and LAP at low LAP on mPAP-LAP relationship. The inflection point of the mPAP-LAP relationship after OA lung injury is equal to the extrapolated pressure intercept on mPAP-CP plots. *(Reproduced with permission from Leeman M, Lejeune P, Closset J, et al. Nature of pulmonary hypertension in canine oleic acid pulmonary edema. J Appl Physiol (1985). 1990;69(1):293–298.)*

of flow that was progressively enhanced at decreasing flow. This curvilinearity was generated via arterial, capillary, and venous distensibility based on experimental data with no need to invoke a closing pressure.

The distensible or compliant model of Zhuang has been shown to predict parallel shifts of mPAP-CO plots to higher pressures, induced by various interventions such as embolism, changes in lung volume, and hypoxia, and even a functional dissociation between PAP and LAP at constant CO.[29,43,44]

Linehan et al. reasoned that previously reported compliant models were too complex, requiring a large number of parameters not identifiable from pressure and flow measurements alone, so that many investigators persisted in using the simpler Starling resistor model of the pulmonary circulation, with its dependence on only two parameters, despite mounting evidence of its inability to model key features of pulmonary pressure-flow relationships.[45] Accordingly, he developed a simpler distensibility model based on only two parameters as well, and showed its adequacy to describe mPAP vs. CO relationships at variable hematocrits in perfused dog lung lobes by the equation:

$$\text{mPAP} = \{[(1 + \alpha \text{PAWP})^5 + 5\alpha \cdot R_0 \cdot \text{CO}]^{1/5} - 1\}/\alpha$$

where the variable hematocrit is captured in the total pulmonary vascular resistance at rest, R_0, and the vessel distensibility α (expressed in % increase in diameter D_0 per mm Hg increase in pressure) is constant throughout the pulmonary vasculature (as has been demonstrated on in vitro mounted vessels):[41]

$$D = D_0 + \alpha \cdot P$$

Nelin et al. showed that Linehan's equation accounted perfectly for measurements of multipoint mPAP vs. CO in isolated pig lungs under normoxic and hypoxic conditions.[46]

An interesting application of this equation is that α can be calculated from the best fit of mPAP, PAWP, and CO measurements obtained during exercise.[47] Invasive and noninvasive studies have shown that a so-calculated α is normally between 1% and 2% per mm Hg higher in young healthy women, and decreases with aging or chronic hypoxic exposure.[48–51] Noninvasive studies have also shown that α is decreased in male subjects of Sub-Saharan African ascendance compared with Caucasian controls,[52] in adolescents conceived by in vitro fertilization,[53] and in healthy subjects exposed to diesel exhaust.[54]

Although α is a small number and the curvilinearity of multipoint mPAP vs. CO plots is slight, a normal value of 2% per mm Hg is associated with a marked decreased in mPAP at high cardiac outputs, such as during strenuous exercise.[50] This is illustrated in Fig. 13-7.

The improved PVR equation has been used to show decreased resistive vessel distensibility in early or latent pulmonary vascular disease.[55] In the study demonstrating these findings, α was, on average, 0.25% per mm Hg in patients with overt PH and pulmonary vascular disease, 0.45% per mm Hg in patients with abnormal lung scintigraphy but no PH, and 1.40% per mm Hg in no-PH controls. Interestingly, α discriminated pulmonary vascular disease with no PH from normal hemodynamics with a sensitivity of 88% and a specificity of 100%. In another study, α was shown to be decreased to an average of 0.4% per mm Hg in PAH and 0.8%–0.9% per mm Hg in heart failure compared with 1.4% per mm Hg in age-matched controls.[56] These results have been independently confirmed.[57] A low α has been shown to be independently associated with a decreased exercise capacity, an altered coupling of right ventricular function to the pulmonary circulation, and a shorter survival.[56,57]

■ Prediction of Vascular Obstruction from Hemodynamic Measurements

The distensibility model of Linehan can be used to estimate the effects of pulmonary vascular obstruction on mPAP over a wide range of cardiac outputs, as shown in Fig. 13-8. At a cardiac output of 5 L/min, mPAP reaches 20 mm Hg at 20%–25% of obstruction and 25 mm Hg at 50% obstruction of the pulmonary circulation.

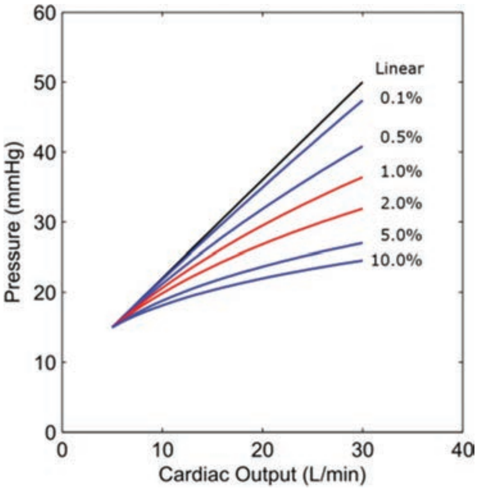

Figure 13-7 Modeled mean pulmonary artery pressure vs. cardiac output relationships at progressively increased distensibility factor α from 0 to 10% per mm Hg. At high flows, slight increases α to 1%–2% (red curves) decreases considerably pulmonary artery pressure, thereby unloading the right heart. *(Reproduced with permission from Naeije R, Vanderpool R, Dhakal BP, et al. Exercise-induced pulmonary hypertension: physiological basis and methodological concerns, Am J Respir Crit Care Med. 2013;187(6):576–583.)*

■ Viscosity

Several equations have been reported to define the relationship between resistance to blood flow, hematocrit, and blood viscosity. The first was reported by Whittaker and Winton in 1933 and was

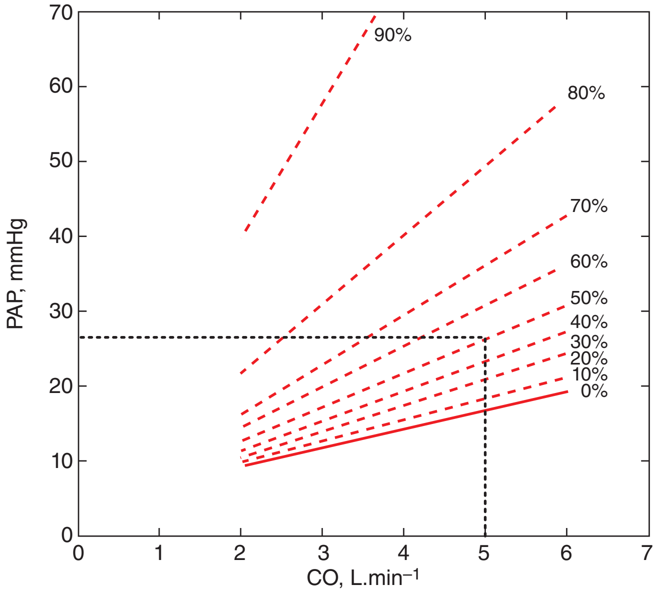

Figure 13-8 Mean pulmonary artery pressure (mPAP)–cardiac output (CO) relationships predicted by the viscoelastic model of Linehan at increasing levels of angiographically determined embolic obstruction. An increase in mPAP above 25 mm Hg corresponding to the definition of pulmonary hypertension occurs after approximately 50% obstruction of the pulmonary vascular bed (see stippled lines). A mPAP of 50 mm Hg as seen in severe pulmonary hypertension corresponds to 80% obstruction. These estimates are for a CO of 5 L/min as the mPAP-obstruction relationship is flow-dependent.

based on measurements on perfused canine hindlimbs at various hematocrits.[58] In these experiments, total resistance (i.e., inflow pressure/flow) at a given hematocrit (R_{HCT}) increased exponentially from plasma perfusate resistance (R_{plasma}) as a function of hematocrit (ϕ):

$$R_{HCT}/R_{plasma} = 0.24/(1 - \phi^{1/3})$$

Linehan et al. repeated the experiments on isolated-perfused lungs of dogs and derived a more pulmonary specific different but still exponential relationship:[45]

$$R_{HCT}/R_{plasma} = \exp(a_1 \cdot \phi)$$

The equations of Whittaker and Winton or Linehan et al. have been shown to yield essentially the same resistance vs. hematocrit relationships. In addition, PVR at a normal hematocrit can be predicted in patients with variable degrees of anemia or polycythemia in a PAWP-dependent manner.[59] A diagram allowing for the prediction of PVR at the normal hematocrit of 45% in anemic or polycythemic patients at PAWP equal either to 5 or 15 mm Hg (taken as extremes of lower and upper limits of normal) is presented in Fig. 13-9.

Because of the exponential relationship between PVR and hematocrit, the impact of hematocrit on PVR increases at high hematocrits or PVR. Furthermore, the increased PAWP makes the PVR vs. hematocrit relationship steeper. For example, a PVR at 1.5 WU at a hematocrit of 20% becomes 3.0 or 4.1 WU at PAWP values of 5 and 15 mm Hg, respectively, at a hematocrit of 45%. At a hematocrit of 70%, PVR becomes approximately 5.5 or 8.4 WU at PAWP values of 5 and 15 mm Hg, respectively.

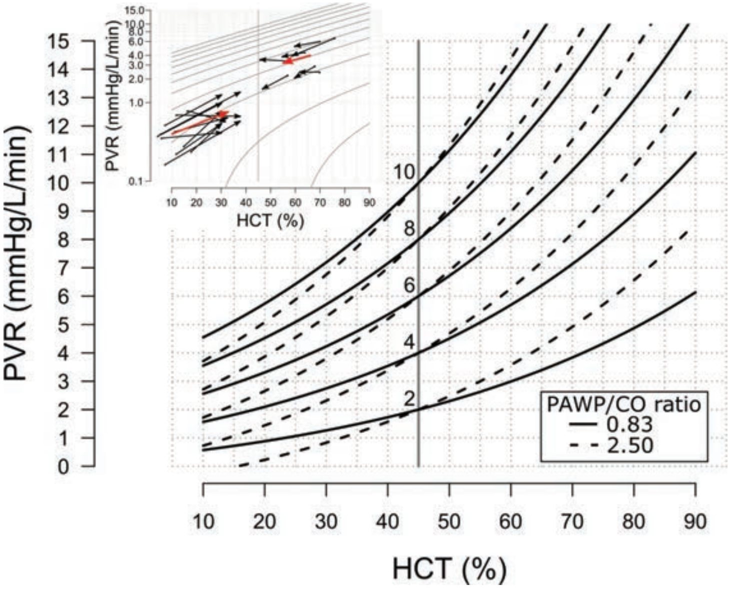

Figure 13-9 Pulmonary vascular resistance (PVR) as a function of hematocrit (HCT). The graphical representation is derived from an exponential relationship previously determined from isolated perfused lung experiments.[52] Iso-PVR lines allow for a prediction of PVR "normalized" for a hematocrit at 45% in anemic or polycythemic patients, at pulmonary artery wedge pressures (PAWP) of 5 mm Hg (full lines) and 15 mm Hg (stippled lines). The window shows log changes in PVR (black arrows, with mean responses as red arrows) previously reported in polycythemic patients after isovolemic hemodilution and in anemic patients after blood cell transfusion. The impact of hematocrit on PVR increases with PVR, PAWP, or hematocrit. Changes in PVR after correction of excessively low or high hematocrit agree on average with the model predictions. *(Reproduced with permission from Vanderpool RR, Naeije R. Hematocrit-corrected Pulmonary Vascular Resistance. Am J Respir Crit Care Med. 2018;198(3):305–309.)*

■ Pulmonary Arterial Compliance

While the distensibility coefficient, α, defines the steady-flow distensibility of small pulmonary resistive vessels, pulmonary arterial compliance (PAC) provides an estimation of pulsatile-flow distensibility of the entire pulmonary vascular bed. Pulmonary arterial compliance (PAC) is usually calculated as a ratio between stroke volume (SV) and pulse pressure (PP), or the difference between systolic and diastolic PAP.

$$PAC = SV/PP$$

This simple equation assumes that the SV is buffered in the large elastic arteries in systole, without any peripheral outflow. However, there is a continuous flow toward the periphery, and the volume increase during ejection is only a fraction of SV. Therefore, SV/PP is a theoretical maximum for pulmonary vascular compliance and overestimates true PAC.

The best method to calculate PAC is based on a two-element Windkessel model: flow waveform and resistance are used as inputs to estimate the compliance value that optimally predicts systolic and diastolic pressures.[60] It has been shown in intact experimental animals at various severities of induced PH that SV/PP overestimates PAC by 60% to 80%.[61]

The afterload of the right ventricle is determined by a dynamic interplay between PVR, PAC, and wave reflections.[62] PAC decreases as a function of increased pulmonary vascular pressures.[63,64] Magnetic resonance imaging–determined proximal arterial compliance amounts to approximately 20% of PAC.[65]

■ The Time Constant of the Pulmonary Circulation

The PAP decay curve in diastole is determined by the product of PVR by PAC. The unit of this product is time and, therefore, is called the arterial time-constant (RC-time).

The inverse hyperbolic relationship between PVR and PAC was first reported in 1971.[66] It is illustrated in Fig. 13-10 and derives from measurements in an anesthetized dog before and after an increase in PVR induced by either embolization with micro-beads or proximal PA ensnarement.[7]

A series of studies have shown that the RC-time is constant over a wide range of severities, etiologies, and treatments of PH.[65–68] The constancy of RC-time implies that PAC becomes a more important

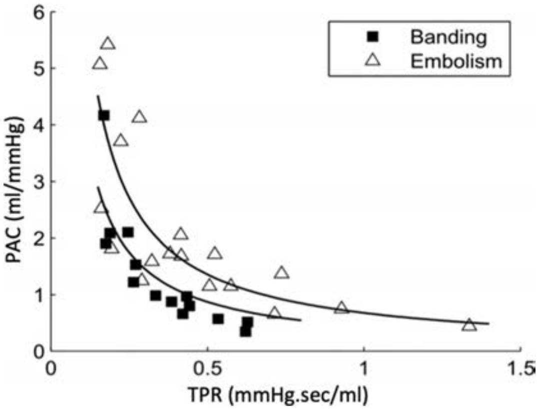

Figure 13-10 Pulmonary arterial compliance (PAC) as a function of total pulmonary vascular resistance (TPR) in dogs with pulmonary hypertension induced either by an ensnarement of the pulmonary arteries (banding, proximal obstruction) or the injection of micro-beads (embolism, (distal obstruction). The time constant PAC × TPR is shorter with proximal obstruction. *(Reproduced with permission from Pagnamenta A, Vanderpool R, Brimioulle S, et al. Proximal pulmonary arterial obstruction decreases the time constant of the pulmonary circulation and increases right ventricular afterload. J Appl Physiol (1985). 2013;114(11):1586–1592.)*

determinant of RV afterload than PVR when PAP and PVR are only modestly elevated,[69] that the pulsatile component of RV hydraulic load is relatively constant,[70] and that the impact of wave reflection on RV afterload is negligible.

The RC-time decreases with proximal PA obstruction, for example in purely proximal thromboembolism[7] or when PAWP increases in patients with HF.[64] This means that PAC decreases out of proportion with increased PVR, and that, accordingly, the oscillatory component of hydraulic load on the RV increases.

Measuring the RC-time is difficult because it is a small number exposed to amplification of errors on measurements of both PAC and PVR. As already mentioned, PAC calculated as SV/PP is almost twice the PAC calculated by the more valid pulse pressure method. On the other hand, PVR is misleading because of the unmet assumptions of linearity and proportionality of the relationships between mPAP and CO and PAWP. Not surprisingly, therefore, RC-times reported in the literature present with considerable variation, casting doubt as to the clinical interest of the measurement in the diagnostic workup of PH.[71]

It has been proposed that the stability of RC-time of the pulmonary circulation may explain the reported tight correlation between systolic, diastolic, and mean PAP (sPAP, dPAP, and mPAP) in normal subjects and in patients with PH of all possible etiologies and severities.[72] The sPAP/mPAP and mPAP/dPAP ratios are, indeed, remarkably stable[73,74] and match actually the golden ratio,[75] with PP equal to mPAP and mPAP predicted from sPAP by the formula:

$$\text{mPAP} = 0.6 \times \text{sPAP} + 2$$

Whether the constancy of RC-time is a satisfactory explanation for the pulmonary circulation's golden ratio remains debated, as the PVR × PAC product shows as much variability as mPAP.[73]

However, the constant proportionality between sPAP and mPAP is useful in clinical practice, as sPAP is easily determined noninvasively from the maximum velocity of tricuspid regurgitation measured by Doppler echocardiography.[76]

■ Pulmonary Vascular Pressure Gradients

The transpulmonary gradient (TPG) or numerator of the PVR equation has traditionally been used for the diagnostic workup of PH:[77,78]

$$\text{TPG} = \text{mPAP} - \text{PAWP}$$

The TPG elucidates the resistive properties of the pulmonary circulation, much like the PVR, when pulmonary blood flow remains within limits of normal. A high cardiac output will spuriously increase the TPG and decrease PVR, while a low cardiac output will have opposite effects.

The limits of normal TPG are not exactly known. The upper limit of normal of TPG was thought to be 10 mm Hg until the 1970s[79] but has since drifted upward to 12 mm Hg,[77] or even, most recently, to 15 mm Hg.[78]

The TPG is sensitive to SV and to PAC. This was modeled in the early 1970s[63] and more recently revisited with a focus on heart failure.[80]

The diagnosis of pulmonary vascular disease is preferably based on the gradient between dPAP and PAWP, or the diastolic pulmonary pressure gradient (DPG). A progressive increase in PAWP would be normally expected to decrease DPG (or TPG) because of vascular distensibility. However, the entire pulmonary vascular tree gets stiffer with increased PAW, thereby increasing TPG while leaving the DPG essentially unchanged or more slightly increased.[80] Thus, a progressive increase in PAWP inevitably increases sPAP, mPAP, and dPAP, with preservation of their relationships. The increase in dPAP is proportionally less than the increase in mPAP (Fig. 13-11).

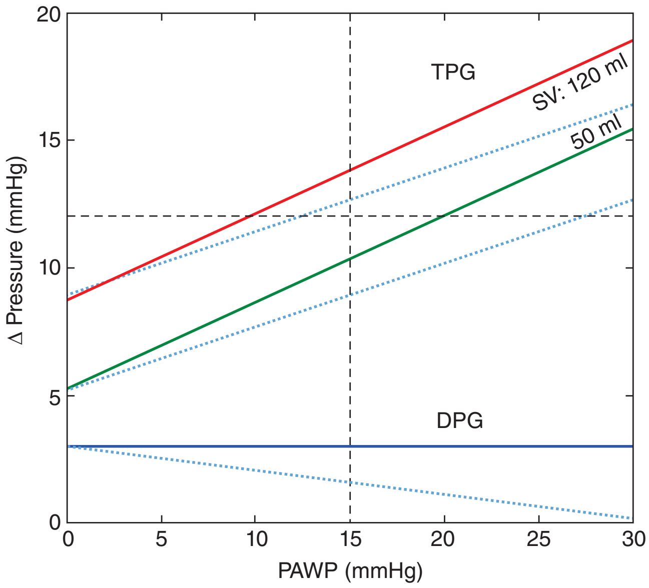

Figure 13-11 Effects of increased pulmonary artery wedge pressure (PAWP) on systolic, diastolic, and mean pulmonary artery pressures (sPAP, dPAP, mPAP) showing progressive increase of the transpulmonary pressure gradient mPAP – PAWP (TPG) with unchanged or decreased (stippled lines) diastolic pressure gradient dPAP – PAWP (DPG). *(Adapted with permission from Naeije R, Vachiery JL, Yerly P, et al. The transpulmonary pressure gradient for the diagnosis of pulmonary vascular disease. Eur Respir J. 2013;41(1):217–223.)*

The DPG was used in the 1970s in combination with PAWP, cardiac output (or arterio-venous oxygen content difference), and blood pressure measurements for the differential diagnosis of cardiac and pulmonary causes of acute respiratory failure.[81] The upper limit of normal of DPG was assumed to be 5 mm Hg,[63] derived from measurements in healthy, athletic young adults. The true upper limit of normal over the entire age range and levels of fitness and ages is probably a few mm Hg higher. A DPG >7 mm Hg has been shown to be associated with a decreased survival in patients with pulmonary hypertension due to left heart conditions.[82]

The diagnosis of pulmonary vascular disease in heart failure best relies on a combination of higher-than-normal PVR and DPG.[83] However, the DPG is difficult to measure, particularly when it is low-normal, prompting clinicians to lose confidence in its diagnostic relevance. A component or precapillary PH that develops on postcapillary PH can then be identified by a PVR calculation alone, albeit with loss of diagnostic accuracy.[84]

■ Gravity

Pulmonary blood flow increases almost linearly from nondependent to dependent lung regions. This inequality of pulmonary perfusion is best demonstrated in an upright lung.[32] The vertical height of a lung averages about 30 cm. The difference in pressure between the extremities of a vertical column of blood of the same size amounts to 23 mm Hg, which is large compared to the mean perfusion pressure of the pulmonary circulation. Accordingly, the physiologic inequality of the distribution of perfusion of a normal lung can be explained by a gravity-dependent interplay between arterial, venous, and alveolar pressures.

At the apex of the lung, alveolar pressure (P_A) is higher than mPAP and pulmonary venous pressure (PVP). In this *zone 1*, flow may be present only during systole, or not at all. Zone 1 is extended in clinical situations of low flow, such as hypovolemic shock, or increased alveolar pressure such as during ventilation with a positive end expiratory pressure. Further caudal in the lung is *zone 2* where

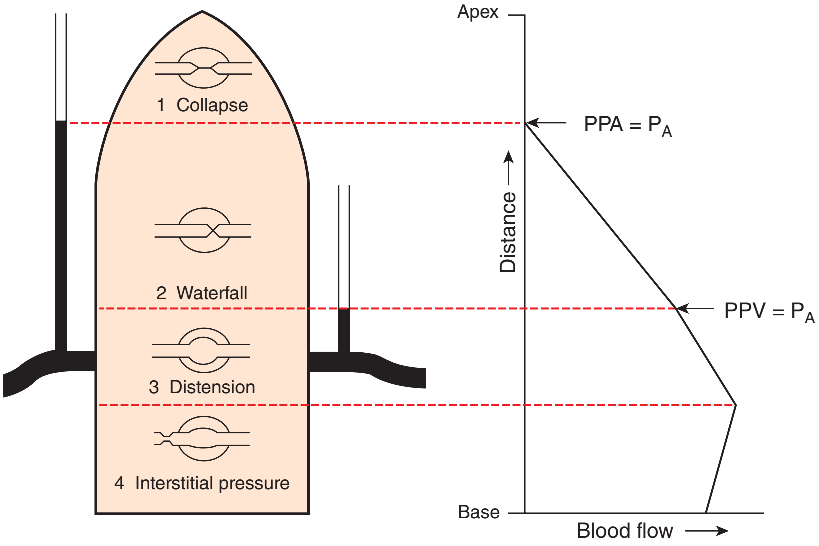

Figure 13-12 Zonal distribution of pulmonary perfusion in an upright lung as determined by the interrelationships between arterial (PAP), alveolar (P_A), and venous pressures (PVP), explaining a gravity-determined progressive increase in perfusion from zones I and II to III. There is a zone IV of decreased perfusion at the most dependent part of the lung. *(Adapted with permission from Hughes JM, Glazier JB, Maloney JE, West JB. Effect of lung volume on the distribution of pulmonary blood flow in man. Respir Physiol. 1968;4(1):58–72.)*

PAP > P_A> PVP. In zone 2, alveolar pressure is an effective closing pressure, and the driving pressure for flow is the gradient between mean mPAP and P_A. As noted previously, such a flow condition can be likened to a waterfall, since PVP, the apparent outflow pressure, is irrelevant to flow, as is the height of a waterfall. In the most caudal portions of the lung, *zone 3*, PVP is higher than P_A, so that the driving pressure for flow is mPAP – PVP. These so-called “West zones” are illustrated in Fig. 13-12.

At the most dependent regions of upright lung, there is an additional region where flow decreases.[85] This *zone 4* has been attributed to an increase in the resistance of extra-alveolar vessels, because it expands when lung volume is reduced or in the presence of lung edema. Active tone may be an additional explanation for zone 4, as it is also reduced by the administration of vasodilators.

The vertical height of lung tissue in a supine human subject is much reduced compared with the upright position. Accordingly, the normal lung constitutes nearly all zone 3; however, there remains a measurable increase in flow from nondependent to dependent lung regions.

Three-dimensional reconstructions using single-photon-emission computed tomography have shown that there is also a decrease in blood flow from the center of the lung to the periphery.[86] High-resolution methods and fractal modeling of the pulmonary circulation have actually led to the notion of a predominantly non-gravity-dependent distribution of pulmonary blood flow.[87] Subtle differences in arterial branching ratios may, indeed, influence flow distribution with increased heterogeneity as the scale of the inquiry narrows, corresponding to the “what is the length of the coastline” effect.[88] However, the overwhelming evidence remains in favor of the thesis that gravity is the single most important determinant of pulmonary blood flow distribution.[88] Vascular geometry–related small-unit heterogeneity of pulmonary blood flow distribution has not been shown to be relevant to gas exchange.

■ Hypoxia

An active intrapulmonary control mechanism is able, to some extent, to correct the passive gravity-dependent distribution of pulmonary blood flow: a decrease in PO_2 increases pulmonary vascular tone. Hypoxic pulmonary vasoconstriction was first demonstrated by von Euler and Liljestrand,[89] who proposed a functional interpretation that can still be considered valid. In lung tissue, PO_2 is determined by a ratio between O_2 carried to the lung by alveolar ventilation ($\dot{V}_A$) and O_2 carried away from the lung by blood flow ($\dot{Q}$):

$$PO_2 = \dot{V}A/\dot{Q}$$

In contrast, with hypoxic vasodilation in systemic tissue local PO_2 is determined by the ratio flow of O_2 carried to the tissues ($\dot{Q}$) and local O_2 consumption ($\dot{V}O_2$):

$$PO_2 = \dot{Q}/VO_2$$

The attributes of hypoxic pulmonary vasoconstriction have been recently extensively reviewed.[90] The hypoxic pulmonary pressor response is universal in mammals and in birds, but with considerable interspecies and interindividual variability. It is intense in pig, horse, and cow, moderate in rodents and humans, and very low in dog, guinea pig, yak, and llama. Chronic hypoxia induces pulmonary hypertension in proportion to initial vasoconstriction. Initial hypoxic vasoconstriction is a quasi-immediate response, with subsequent modulation depending on the experimental model or preparation. Hypoxic vasoconstriction strengthens during the first few hours of hypoxic exposure in humans. The temporal sequence of hypoxia-induced remodeling is less well known. After 6 hours of hypoxic exposure, re-oxygenation immediately decreases PVR without, however, a complete return to normal.[91] The reversibility of increased PVR with re-oxygenation is largely lost after 24 to 48 hours exposure to hypoxia.[18]

Hypoxic vasoconstriction is observed in lungs devoid of nervous connections and, indeed, also in isolated pulmonary arterial smooth muscle cells.[90] The response is enhanced by acidosis, a decrease in mixed venous PO_2, repeated hypoxic exposure (in some experimental models), perinatal hypoxia, decreased lung segment size, cyclooxygenase inhibition, nitric oxide inhibition, and by certain drugs or mediators, which include almitrine and low-dose serotonin. The response is inhibited by alkalosis, hypercapnia, an increase in pulmonary vascular or alveolar pressures, vasodilating prostaglandins, nitric oxide, complement activation, low-dose endotoxin, calcium channel blockers, β_2 stimulants, nitroprusside, and, paradoxically, by peripheral chemoreceptor stimulation. The hypoxic pressor response is biphasic, with a progressive increase as PO_2 is progressively decreased to approximately 35 to 40 mm Hg, followed by a decrease (“hypoxic vasodilatation”) in more profound hypoxia.

The hypoxia-induced increase in PVR is mainly caused by a constriction of precapillary small arterioles.[90] Small pulmonary veins also constrict in response to hypoxia, but this does not normally contribute to more than 20%–30% of the total change in PVR.[92]

While hypoxic pulmonary vasoconstriction has been shown to be an only moderately efficient feedback mechanism,[93,94] it may still produce substantial improvements in arterial oxygenation of patients with inhomogeneous lungs, such as in chronic obstructive

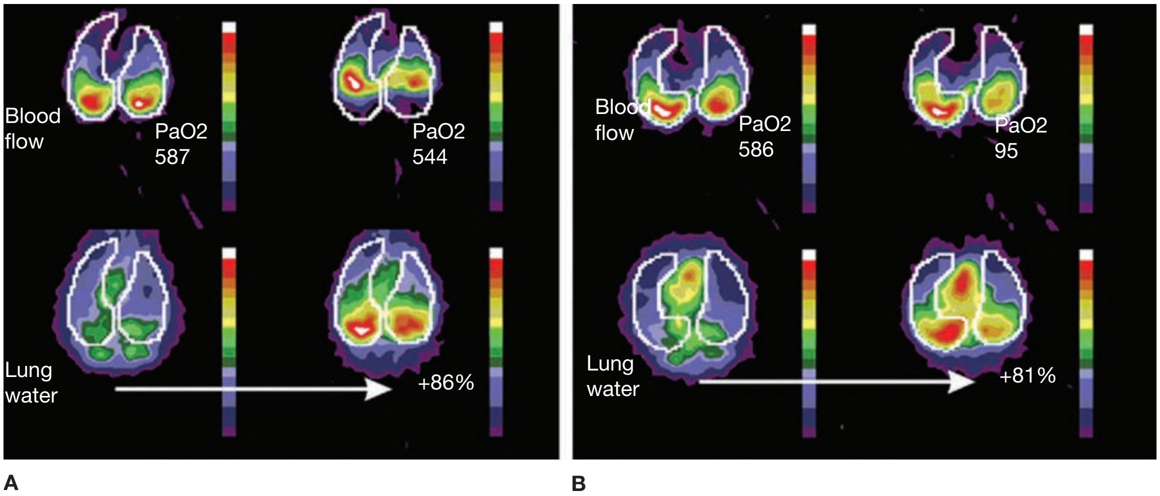

Figure 13-13 PET scan measurements of blood flow and lung water in a supine dog before and after induced of acute lung injury, with preserved hypoxic vasoconstriction (**A**) or without hypoxic vasoconstriction (**B**). In the normal lung, blood flow and water increase to the most dependent lung regions (from blue to red). Acute lung injury approximately doubles lung water, but arterial PO_2 (PaO_2) is preserved because of a hypoxic vasoconstriction redirecting flow to better-aerated lung regions. Prevention of hypoxic vasoconstriction increases flow to the dependent edematous lung regions, and this is associated with a marked decrease in PaO_2. *(Reproduced with permission from Gust R, Kozlowski J, Stephenson AH, et al. Synergistic hemodynamic effects of lowdose endotoxin and acute lung injury. Am J Respir Crit Care Med. 1998;157(6 Pt 1):1919–1926.)*

pulmonary disease (in which hypoxemia is explained mainly by low V_A/Q ratios) or in the acute respiratory distress syndrome, ARDS (in which hypoxemia is explained mainly by V_A/Q ratios equal to zero, i.e., shunt).[95]

Topographic blood flow distribution (assessed with PET scanning) and arterial PO_2 can be shown to conform to the expected functional effects of hypoxic pulmonary vasoconstriction in experimental acute lung injury models, as an inhibition of the response prevents redistribution of blood flow to nondependent lung regions and markedly aggravates shunt and arterial hypoxemia.[96] This is illustrated in Fig. 13-13 in an experiment that also shows the predominant effects of gravity on the distribution of pulmonary blood flow and its relevance to gas exchange.

The biochemical mechanism of hypoxic pulmonary vasoconstriction remains incompletely understood.[90] Current thinking is that a decrease in PO_2 inhibits smooth muscle cell voltage-gated potassium channels, resulting in membrane depolarization, influx of calcium, and cell shortening. However, the nature of the low PO_2 sensing mechanism remains elusive. Mitochondria and nicotinamide adenine dinucleotide phosphate oxidases are discussed as oxygen sensors. Reactive oxygen species, redox couples, and adenosine monophosphate–activated kinases are candidate mediators. The reversal of hypoxic vasoconstriction by profound hypoxia is due to an activation of ATP-dependent potassium channels.

Normal and abnormal pulmonary vascular tone have been shown to be modulated by a series of endothelium-derived and circulating mediators.[90] Endothelium-derived relaxing factors include nitric oxide, prostacyclin, and the endothelium-derived hyperpolarizing factor. The major endothelium-derived contracting factor is endothelin. These observations have been at the basis of efficient treatments of pulmonary arterial hypertension using prostacyclin derivatives, phosphodiesterase-5 inhibitors to enhance nitric oxide signaling, and endothelin receptor blockers.

Hypoxic pulmonary vasoconstriction serves to limit the perfusion of fetal lungs. That hypoxic pulmonary vasoconstriction matters to the outcome of lung diseases has not been demonstrated. Persistent whole-lung hypoxic vasoconstriction at high altitudes may be a cause of "fixed" pulmonary hypertension in proportion to initial pressor response.[97] High altitude is generally mild or borderline in the human species[98] and, thus, of uncertain clinical relevance.

■ Autonomic Nervous System Control

The pulmonary circulation is richly innerved by the autonomic nervous system, which includes adrenergic, cholinergic, and nonadrenergic noncholinergic signaling systems.[99] However, the role played by the autonomic nervous system in the control of pulmonary vascular tone remains incompletely understood. Sympathetic nervous system activation does not affect PVR but stiffens the proximal pulmonary arterial tree.[100]

Distension of the proximal pulmonary arterial tree causes distal vasoconstriction, which can be inhibited by chemical or surgical sympathectomy.[101,102] This pulmonary reflex is believed to contribute to high fetal PVR and to slow postnatal pulmonary vasodilation and the associated risk of lung edema. It has been invoked to explain reverse pulmonary vascular remodeling after pulmonary artery banding in infants born with congenital left-to-right cardiac shunts.[103] It offers rationale for current attempts at treating PH by PA denervation.[104]

■ Exercise

Exercise is associated with an increase in cardiac output in response to increased oxygen uptake ($\dot{V}O_2$). Therefore, pulmonary blood flow CO is increased during exercise. This is necessarily associated with an increase in PAP and, to a lesser extent, PAWP. However, exercise is also associated with increased ventilation, changes in lung volumes, and sympathetic nervous system activation with systemic hemodynamic changes, all of which affect pulmonary vascular pressure-flow relationships.[105]

The stress of exercise on the pulmonary circulation is mediated by an increase in cardiac output. This is true for dynamic exercise such as cycling, running, or swimming. Resistive or static exercise, such as weightlifting and handgrip strengthening, is associated with increases in cardiac output too small to stress the pulmonary circulation[106] and may, furthermore, be associated with confounding effects of increased intrathoracic pressure and systemic blood pressure.[107]

Exercise stress testing of the pulmonary circulation to diagnose latent or early pulmonary vascular disease has to conform to a series of methodologic constraints. Body position does not matter, as the same maximum $\dot{V}O_2$ and cardiac output are measured during incremental cardiopulmonary exercise testing in supine or semirecumbent positions.[24] Maximum workload is actually lower semirecumbent, but this is not relevant to the pulmonary vascular function as defined by pulmonary vascular pressure-flow relationships.[24] Measurements should be done during, not after, the exercise stress, as post-exercise recovery of vascular pressures and flows normally occurs within minutes.[108] Exercise stress should be incremental.[49,50,105] Prolonged steady-state exercise may be associated with a progressive decrease in pulmonary vascular pressures in relation to a decreased pulmonary blood volume, as the systemic circulation adapts and does not offer the improved accuracy of a range of pressure-flow coordinates to define pulmonary vascular function.[109,110]

Since CO, workload, and $\dot{V}O_2$ are (quasi-) linearly related as long as CO is not too high, and cardiac output measurements during exercise are challenging, either workload[111,112] or $\dot{V}O_2$[113] are sometimes used as surrogates for CO to describe pulmonary vascular function. Equations to predict CO have been derived from linear regressions on measurements during exercise in healthy volunteers:[24]

$$\text{CO (L/min)} = 0.34 \times \dot{V}O_2\ \text{(mL/kg/min)} + 5.4$$
$$\text{CO (L/min)} = 0.06\ \text{Workload (W)} + 6.5$$

However, CO vs. workload and CO vs. $\dot{V}O_2$ relationships tend to plateau at high levels of exercise, and interindividual variability of these relationships alters the reliability of the prediction.[24] For example, at a $\dot{V}O_2$ of 20 mL/kg/min or a workload of 100 W, CO may vary between 8 and 16 L/min, making estimation of CO excessively imprecise.[24,48–50]

Noninvasive exercise stress testing of the pulmonary circulation using Doppler echocardiography is acceptable, as exercise measurements are probably accurate[48–50] even though this has been rigorously demonstrated for all the components of the PVR equation only in resting conditions.[114] Echocardiographic estimates of PAP from the maximum velocity of tricuspid regurgitation during exercise have recently been shown to be accurate, but with limited precision.[112]

Doppler echocardiography may underestimate cardiac output during exercise.[111] Another concern is the possible occurrence of a gradient between systolic RV and PAP, particularly at high cardiac output and in the upright position.[115,116] This will need to be confirmed with high-fidelity micro-manometer-tipped catheters.

Exercise is associated with increased ventilation and pleural pressure–dependent pulmonary vascular pressure swings, which make the interpretation of pulmonary vascular pressure curves difficult. Averaging vascular pressures over several respiratory cycles instead of reading them at end-expiration largely allows cancelling out the influence of negative inspiratory and positive expiratory pleural pressures.[11,15] Zero leveling in different body positions may be a challenge. Computed tomography has offered easy-to-implement, three-dimensional guidance.[11] Zero leveling is not a problem for echocardiographic estimates of systolic PAP from recalculated trans-tricuspid gradients.

Most of the information from a set of pulmonary vascular pressure pressure-flow coordinates during exercise is captured by the slope of a linear adjustment.[49,50,105,117] Invasive, as well as noninvasive, studies have shown that slopes on mPAP-CO relationships in healthy subjects are, on average, about 1.5 mm Hg/L/min; limits of normal range from 0.5 to 3 mm Hg/L/min.[49,50,105,117,118] These values correspond to a maximum exercise total PVR (TPVR) of no more than 3 Wood units, or a mPAP of 30 mm Hg at a CO <10 L/min. Combining all these criteria actually strengthens the discrimination between normal and abnormal responses.[117]

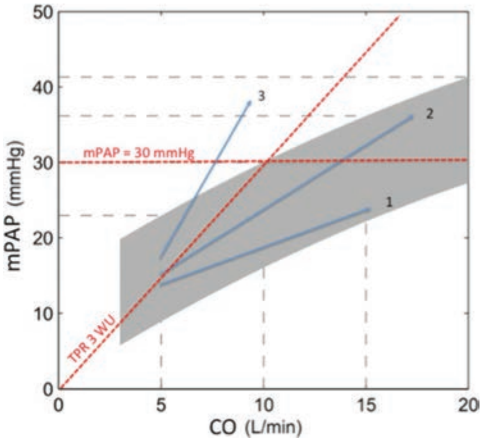

Figure 13-14 Mean pulmonary artery pressure (mPAP) as a function of cardiac output (CO) in 3 subjects (arrows): 1 and 2 are normal, even if 2 has exercise mPAP >30 mm Hg, and 3 has an abnormal response suggesting exercise-induced pulmonary hypertension. Limits of normal are within the shaded area. *(Reproduced with permission from Lewis GD, Bossone E, Naeije R, et al. Pulmonary vascular hemodynamic response to exercise in cardiopulmonary diseases. Circulation. 2013;128(13):1470–1479.)*

Theoretical normal and abnormal linearized mPAP vs. CO relationships in individuals with normal resting mPAP are illustrated in Fig. 13-14.

The upper limit of normal of PAWP during exercise is generally considered to be between 15 and 20 mm Hg, but higher values can be recorded in athletes and in elderly subjects.[20,49,50] A higher cutoff value of 25 mm Hg has been proposed for the diagnosis of heart failure.[119–121] A flow-corrected measure may be more appropriate.[50] Given the average proportional difference between mean mPAP vs. CO and PAWP vs. CO relationships, a slope of 2 mm Hg/L/min is the upper limit of normal of PAWP vs. CO.[105] This cutoff value has been confirmed in studies on young and old male and female healthy volunteers[122] and patients with heart failure compared with healthy controls.[123]

■ Pulsatile Flow Pulmonary Hemodynamics

The study of the pulmonary circulation as a steady-flow system is a simplification. Pulmonary pulse pressure, or the difference between sPAP and dPAP, is on the order of mPAP, as compared with less than half the value in the systemic circulation. Instantaneous pulmonary blood flow varies from a maximum at mid-systole to around zero in diastole.

The morphology of pulmonary pressure and flow waves changes with the development of pulmonary hypertension. In patients with severe PH, the RV pressure wave is characterized by a sharp initial upstroke, followed by a short plateau and by a late systolic peaking; the PA pressure wave is characterized by a huge pulse pressure and a late systolic peaking, as well,[124] while the pulmonary flow wave presents a shortened acceleration time and late or midsystolic deceleration.[125] In the most severe forms of PH, the PAP appears "ventricularized."[124] These morphologic aspects are entirely explained by the combined effects of decreased compliance[126] and wave reflection.[127]

A complete evaluation of pulmonary vascular function relies on the calculation of the relationship between pulsatile pressure and flow or pulmonary vascular impedance (PVZ), instead of the relationship between mean pressure and flow as used in the PVR equation.

Pulmonary vascular impedance, PVZ, is calculated from a spectral analysis of the pulmonary arterial pressure and flow waves.[128] This analysis is possible because the pulmonary circulation behaves nearly linearly. This means that a purely sinusoidal

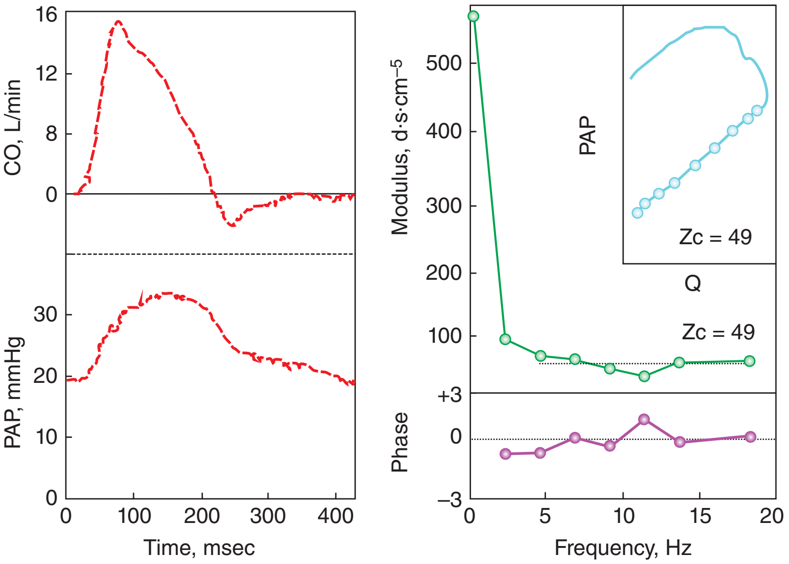

Figure 13-15 Pulmonary artery flow (CO) and pressure (PAP) waves (left panel) and pulmonary arterial input impedance spectrum (right panel). At 0 Hz the total PVR is obtained (mean pressure over mean flow). Between 0 and 4 Hz the impedance is determined mainly by total arterial compliance. The averaged input impedance for high frequencies, usually taken between 4 and 8 Hz, equals the characteristic impedance (Zc). The oscillation of the impedance about the characteristic impedance results from wave reflection. Zc is also the slope of early systolic PAP-flow relationship.

flow oscillation produces a purely sinusoidal pressure oscillation of the same frequency. The sinusoidal pressure and flow waves can be related by the ratio of their amplitudes (modulus) and the difference in their phases (phase angle). A typical PVZ spectrum is illustrated in Fig. 13-15.

Pulmonary arterial impedance at zero Hz, Z_0, (the ratio of mean pressure to mean flow, mPAP/Q) corresponds to TPVR. This parameter is mainly determined by the small resistance vessels, as well as LAP. As frequency increases, the impedance is affected by more proximal elements of the arterial tree. The modulus of the impedance decreases rapidly from Z_0 to a first minimum at 2–3 times the heart rate and then oscillates about a constant value. The impedance phase increases from a negative value at low frequencies, indicating that flow leads pressure to zero at higher frequencies. The precipitous fall in modulus and the negative phase of the impedance are a measure of pulmonary artery compliance. At high frequencies the rather constant modulus and nearly zero phase angle are a measure of the proximal arterial compliance.

The impedance modulus at high frequencies, when impedance phase is nearly zero and, therefore, wave reflections can be ignored, is the characteristic impedance Z_C. It is typically measured as the average modulus at higher frequencies (usually 10–20 times the heart rate). It can also be measured as the slope of the early systolic pulmonary artery pressure-flow relationship in the time domain.[129]

The oscillations of the impedance modulus about its mean value result from distinct wave reflections. Increased magnitude of these oscillations implies increased reflections. A shift of the first minimum of modulus to higher frequencies indicates an increased wave velocity or a decreased distance to the dominant reflection site.

Distal small vessel obstruction, such as that caused by microembolism, hypoxia, or PAH increase Z_0 but have limited effects on the PVZ spectrum; some shift may be noted of first minimum and maximum of PAP/Q to higher frequencies, along with unchanged or, sometimes, even a decrease in Zc.[130–132] Proximal vessel disease, such as that mimicked by experimental proximal ensnarement of the pulmonary arteries or clinical chronic thromboembolic pulmonary hypertension (CTEPH), shifts the entire PVZ spectrum to higher ratios of pressure and flow moduli.[130] Very high PAP due to major peripheral small vessel obstruction also increases Z_c because of extreme stiffening of the pulmonary arteries and increased reflected wave speed.[131,132]

Exercise has been reported in an animal study to decrease PVR but to shift the PVZ spectrum to higher pressure and flow moduli at all frequencies with an increase in Zc, a shift of the first minimum of the ratio of pressure, and flow moduli to higher frequencies and more negative phase angle.[133] The increase in Zc is explained by a decreased area compliance of the proximal pulmonary arterial tree because of increased distending pressure related to increased flow, with a possible contribution of exercise-associated sympathetic nervous system activation. Exercise has been reported to be associated with unchanged Zc in a small human study.[134] Exercise is also associated with a greater decrease in PAC than in PVR, which results in a decreased RC-time and increased RV hydraulic load.[135] The apparent discrepancy between changes in Zc and PAC is explained by the sensitivity of Zc to proximal stiffness and dimensions, while PAC integrates the distensibility of the entire pulmonary circulation.

■ Right Ventricular Function

The RV is functionally coupled to the pulmonary circulation. Because of the normally low pulmonary vascular pressures taking the entire cardiac output, the RV acts as a thin-walled flow generator. The structural and functional characteristics of the RV allow for the accommodation of large increases in flow, less so small increases in afterload. However, the basic laws of the heart remain applicable, i.e., rapid beat-to-beat heterometric adaptations (Starling's law of the heart) and otherwise progressive structural and inotropic homeometric adaptations (Anrep's law of the heart) to changes in loading conditions. Thus, RV adaptation to pulmonary hypertension is homeometric with increased contractility, eventual hypertrophy, and preserved dimensions. Failure of this mechanism, depending on rate of onset and magnitude of increase in PAP, requires heterometric adaptation, with increased RV dimensions and systemic congestion.[136,137]

Right Ventricular Hydraulic Load

Increased PAP requires increased RV hydraulic power to sustain adequate forward flow. Hydraulic power is made of two components: the energy per unit time (power) to produce steady flow, which is the product of mPAP and SV, and the power to produce the pulsatile component of PAP and SV.[138] The latter can be calculated from the difference between the product of the integrations of instantaneous PAP and SV waves and the product of mPAP and SV.

Since mean flow determines oxygen transport, mean power may be considered useful, whereas oscillatory power is "wasted." As a consequence, the ratio of oscillatory (W_{OSC}) to mean (W_{MEAN}) power, or W_{OSC} to total (W_{TOT}), should preferably be small.

Because of the proportional relationship between systolic, diastolic, and mPAP, the ratio of W_{OSC} to W_{TOT} should remain constant. This was indeed reported by Saouti et al.[70] in a total of 49 patients with pulmonary hypertension of variable severity. Total power increased with severity of pulmonary hypertension, but the ratio of W_{OSC} to W_{TOT} remained at 23%. Accordingly, the authors proposed that W_{OSC} should be equal to 1.3 times W_{MEAN} in all circumstances.

$$W_{TOT} = 1.3 \times \text{mPAP} \times \text{SV}$$

Extremes of reported RC-times, ranging from 0.2 to 1.0 s, affect the proportionality constant between W_{TOT} and W_{MEAN} from only 1.2 to 1.4.[139] Thus, changes in PAC at any given level of PVR have a minimal effect on the oscillatory component of RV hydraulic load.

Right Ventriculo-Arterial Coupling

The calculation of power includes a measurement of cardiac output and, thus, depends not only on the mechanical properties of the pulmonary circulation but also on ventricular function. It has been suggested that power transfer and ventricular efficiency are near maximal in normal subjects. A simplified approach to test this has been given by Sunagawa et al.[140] and Suga et al.[141] These authors proposed a graphical analysis based on the ventricular pressure-volume diagram and a characterization of the arterial system by means of its arterial elastance.

The diagram allows for the determination of maximal or end-systolic ventricular elastance (Ees) as a load-independent measurement of contractility, and of arterial elastance (Ea) as a measurement of afterload as it is “seen” by the ventricle, as well as calculation of an Ees/Ea ratio as a measurement of the coupling of ventricular to arterial function. This analysis is equally valid for the RV and the LV.[141,142]

Mathematical modeling shows that the optimal matching of systolic ventricular and arterial elastances occurs at an Ees/Ea ratio around 1.5. An isolated increase in Ea or decrease in Ees, or a decrease the Ees/Ea ratio, indicates uncoupling of the ventricle from its arterial system. If all other measurements are the same, a decrease in Ees/Ea is necessarily accompanied by a decrease in SV. On the other hand, an isolated increase in preload is associated with an increase in SV with unaltered ventriculo-arterial coupling.

The complex geometry of the RV makes functional evaluations with measurement of instantaneous volume changes technically difficult, and the determination of Ees may be unreliable because of the particular shape of the RV pressure-volume loop and non-coincidence of end-ejection and end-systole. This problem can be overcome by measuring pressure-volume loops at several levels of preload,[142] but bedside manipulations of venous return are too invasive to be ethically acceptable. In addition, when applied to intact beings, changes in venous return are associated with reflex sympathetic nervous system activation, which affects the ventricular function that is measured.

These concerns have been addressed by a single beat method allowing for a direct quantification of the coupling of the RV to the pulmonary circulation.[143] The approach had been initially proposed for the left ventricle.[144] In its principle, the method avoids absolute volume measurements and related technical complexities in calculating Ees and Ea from instantaneous RV pressure and flow output measurements. As shown in Fig. 13-16, a Pmax is estimated from a nonlinear extrapolation of the early and late systolic isovolumic portions of the RV pressure curve. This estimated Pmax has been shown to be tightly correlated with Pmax directly measured during a non-ejecting beat.[143] A straight line drawn from Pmax to the RV pressure versus relative change in volume curve allows for the determination of Ees. A straight line drawn from the Ees point to the end-diastolic relative volume point determines Ea (Fig. 13-16).

The Ees/Ea ratio as determined by the single beat method has been shown to be decreased by propranolol and increased by dobutamine and maintained in the presence of increased Ea due to hypoxic pulmonary vasoconstriction.[143] In fact, Ees increases adaptively to increased Ea in hypoxia, even in the presence of adrenergic blockade, which is compatible with the notion of homeometric adaptation of RV contractility.

Kuehne et al. used cardiac magnetic resonance (CMR) imaging together with RV pressure measurements with Pmax calculations to generate pressure-volume loops and Ees and Ea determinations in patients with PAH.[145] As compared with controls, Ees was almost doubled, but Ees/Ea was decreased, indicating insufficient homeometric adaptation and pending RV failure.

The Right Ventricular Pump Function Graph

An alternative approach was developed by Elzinga and Westerhof in 1978.[146] The authors described RV pump function curves by plotting mean RV pressure as a function of SV. As shown in Fig. 13-17, the pump function curve is built from measurements of mean RV pressure and SV, a calculated maximum pressure at zero SV, and a parabolic extrapolation to a zero pressure SV. In this representation, an increase in preload shifts the curve to greater SV with no shape change, while an increased contractility leads to a higher maximum pressure with no change in maximum SV. This analysis has been used to explain more severe RV failure in the face of lower mPAP in PH associated with systemic sclerosis, as explained by myocardial involvement by the disease process.[147]

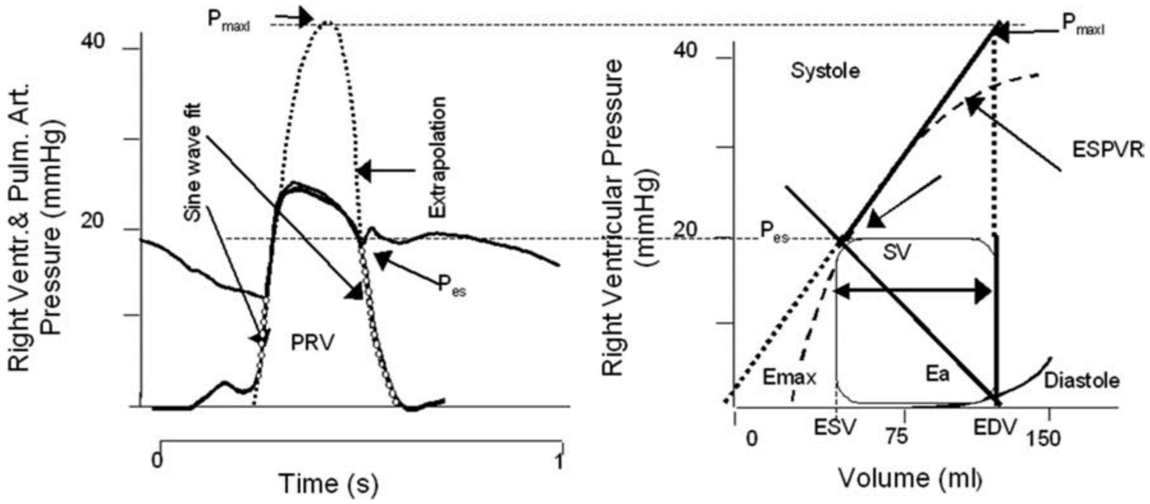

Figure 13-16 Single beat method to measure right ventriculoarterial coupling. A maximum pressure (*P*max) is calculated from nonlinear extrapolation of early and late isovolumic portions of the right ventricular pressure curve. A straight line is drawn from *P*max and the end-diastolic volume (EDV) to *P*es (end-systolic pressure) and the end-systolic volume, thus *E*max (maximum or end-systolic elastance) = (*P*max −*P*es)/SV, where SV is the stroke volume. The arterial elastance *E*a is defined by the ratio *P*es/SV.

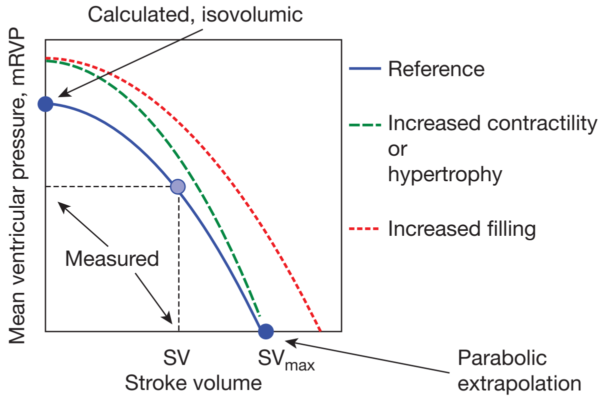

Figure 13-17 Pump function curve defined by mean right ventricular pressure as a function of stroke volume. The zero-stroke volume point is calculated from a maximum pressure determination (see Fig. 13-16). The zero pressure point results from a parabolic extrapolation, from measured and zero stroke volume points. *(Data from Elzinga G, Westerhof N. The effect of an increase in inotropic state and end-diastolic volume on the pumping ability of the feline left heart. Circ Res. 1978;42(5):620–628.)*

Simplified Estimates of Right Ventriculo-Arterial Coupling

Both the ratio of end-systolic to arterial elastance and the pump function graph are not readily clinically applicable. Therefore, clinicians use simplified bedside estimates of RV-arterial coupling.

Ees/Ea may be simply expressed as a ratio of volumes. Sanz et al. reported on assessment of RV-arterial coupling estimated by the ratio of SV to end-systolic volume (ESV), as measured by CMR in 139 patients referred for PH. The resulting volume-determined Ees/Ea or SV/ESV was shown to decrease progressively with increasing severity of PH.[148]

Since ESV is equal to end-diastolic volume (EDV) minus SV, the SV/ESV ratio is necessarily related to ejection fraction (EF) or SV/EDV:[149]

$$\text{Ees/Ea} = \text{SV/ESV} = \text{EF}/(1 - \text{EF})$$

Another manipulation of the Ees/Ea equation allows for the calculation of EV/ESV or EF from an RV pressure curve:

$$\text{Ees/Ea} = \text{Pmax/mPAP} - 1$$
$$\text{EF} = 1 - \text{mPAP/Pmax}$$

where mPAP approximates end-systolic pressure.[150,151]

A progressive decrease in either EF or SV/ESV is inevitably associated with increased ESV and end-diastolic volume EDV. This is modeled to occur at an EF <35% or SV/ESV ratio <52% when SV is preserved.[149] High-fidelity measurements of pressures and volumes using conductance catheter technology have confirmed that the coupling of the RV to the pulmonary circulation has a lot of reserve, as RV Ees/Ea or EF decrease to critical values of approximately 0.8 or 35% before RV dimensions increase above normal and symptoms of systemic congestion appear.[152,153]

Measurements of RV-PA coupling by gold standard methodology[152] are demanding, and pressure or volume surrogates rely on assumptions that may alter their clinical relevance.[153] Accordingly, entirely noninvasive surrogates, such as the tricuspid annular plane systolic excursion (TAPSE) to estimate contractility, and systolic PAP to estimate afterload (both of which are easily assessed during a transthoracic echocardiographic evaluation[154]) have been validated[155,156] and shown to be of great prognostic relevance in heart failure,[83,154,155] PAH,[157] and PH in chronic lung diseases.[158]

SUMMARY

The pulmonary circulation is a high-flow and low-pressure circuit, with an average resistance of 1 mm Hg·min·L^{-1} in young adults that increases to 2.5 mm Hg·min·L^{-1} over 4–6 decades of life. Pulmonary vascular mechanics are best described by pulmonary vascular pressure-flow relationships conforming to distensible vessel models with a correction for hematocrit. The product of pulmonary arterial compliance and resistance is constant, but it decreases slightly as a cause of increased pulsatile hydraulic load in the presence of increased venous pressure or proximal pulmonary arterial obstruction. Left atrial pressure is transmitted upstream to pulmonary artery pressure in a less than 1:1 ratio in steady flow conditions, but in a higher than 1:1 ratio in pulsatile flow conditions. The distribution of pulmonary perfusion is mainly determined by the effects of gravity and corrected to some extent by hypoxia-induced vasoconstriction to preserve matching to regional decrease in ventilation. Exercise is associated with a decrease in pulmonary vascular resistance. Right ventricular function is coupled to the pulmonary circulation, with an optimal ratio of end-systolic to arterial elastance of 1.5–2.

CHAPTER 14

Ventilation, Pulmonary Blood Flow, and Ventilation–Perfusion Relationships

Peter D. Wagner

This chapter presents the physiologic basis of normal pulmonary gas exchange. Gas exchange occurs by an integrated series of gas transport steps between the environmental air we breathe and the Hb molecule of the red cells passing through the pulmonary capillaries. These transport steps are of two types—diffusive and convective—and a number of conceptually separate diffusive as well as convective processes interact to accomplish the gas exchange mission. This is true both for gases that are taken up from the environment into the blood (i.e., O_2 and occasional toxic gases or volatile anesthetics) and for gases that are eliminated from the body (i.e., CO_2 and volatile anesthetic agents).

This chapter deals principally with the convective processes and Chapter 16 with those involving diffusion. However, since the two types of process occur simultaneously, they are closely linked.

BASIC OUTLINE OF THE GAS EXCHANGE PATHWAY

This section dwells on O_2, being the gas of principal physiologic interest. However, the pathway components are of course identical for all gases and furthermore do not depend on whether the gas is being taken up (O_2) or eliminated (CO_2). On the other hand, distinct quantitative differences in the uptake or elimination patterns of different gases exist, but those are readily explained by differences in their fundamental physical or chemical properties, and not by transport pathway differences.

To understand the gas transport pathway one must first appreciate the anatomy of the lungs, laid out in detail in Chapter 2. The salient functional features are presented in Fig. 14-1.

The chest wall (rib cage and diaphragm) contains muscles that on contraction expand the volume of the chest cavity and thus reduce the hydrostatic pressure of the pleural space, expanding the lungs with air drawn in via the mouth and nose. Although there is but a single air passage in the neck (i.e., the trachea), this soon branches into right and left main bronchi. These also divide many times, essentially dichotomously. There are some 16 such orders of branching of these bronchi, resulting in a structure that resembles an inverted deciduous tree without its leaves in winter.[1] With each successive branch the airways become shorter and narrower, but ever greater in number, usually doubling at each branching. Thus, although the cross-sectional area of any one airway becomes smaller with each branching, the greater number of airways more than makes up for loss of individual cross-sectional area such that the sum of cross-sectional areas of all airways of a given generation rises essentially exponentially with each branching (Fig. 14-2). The total volume of gas in these 16 conducting airway generations is called the anatomic or conducting airway dead space and approximates 1 mL per pound of body weight. After these 16 or so successive branches, the tubular, purely conducting airways begin to show alveolar units in their wall (generations 17–19 or so) and these finally give way to fully alveolated structures (in succession: alveolar ducts, alveolar sacs, and alveoli). There are some 500 million alveoli, each about 300 μm in diameter. They are blind structures so that ventilation has to be accomplished by a tidal, in-and-out process (rather than a flow-through process as for pulmonary blood flow). The alveoli can be seen in Fig. 14-1, from a different perspective. For gas exchange to occur, O_2 must be moved from the mouth all the way to the alveoli—it is only within alveoli that gas exchange occurs.

Each alveolus is densely covered in a capillary network, seen from various perspectives in Fig. 14-1. This network is closely applied to the alveolar gas space as Fig. 14-1 shows, with on average only about 1/2 μm of cellular and interstitial tissue between the blood inside the capillary and the alveolar gas outside.[2] The capillary network is fed by the pulmonary arterial tree which branches alongside the airways in a very similar pattern as the airways. The capillaries then drain into venules that join to form larger and larger vessels, eventually becoming the pulmonary veins that drain oxygenated blood into the left atrium. This coalescence of venous vessels forms a similar branching tree to the pulmonary arteries and airways, but in reverse. The right ventricle is responsible for unidirectional pumping of blood through this vascular system.

The gas exchange pathway from the lips to the left atrium is therefore highly complex structurally; understanding how gases pass along the pathway requires following the events an O_2 molecule must participate in between the lips and the left atrium.

1. The first step is inspiration of air into the trachea via mouth and nose. Accomplished by inspiratory chest wall muscle contraction that reduces intrathoracic pressure, this step is convective (like water flowing from a region of high to low pressure along a garden hose). All the respired air must pass the trachea but at the first branch point some air goes to the right lung, the rest to the left. At each successive branch point, similar mass-conserving distribution of air must occur between the daughter branches of each parent pathway. Remembering that there are some 23 total branchings from the mouth to the 300 million alveoli, there is a very real risk of quite uneven distribution of that inspired air amongst those alveoli.[3] The principal determinants of how air is distributed at branch points (i.e., between daughter branches) are the mechanical properties of the respiratory system: the compliance (elastic properties), the resistance, and the inertial properties. These concepts are more fully treated in Chapter 10.
2. During normal resting inspiration, flow is laminar in most of the airways. Thus, inspired gas develops a parabolic profile due to higher molecular velocities in the center than periphery of the airway (Fig. 14-3). The parabolic "tongue" of inspired gas in Fig. 14-3 moves down an airway, while around the tongue is gas remaining from the previous expiration. The tongue therefore has O_2 at a concentration of 21% and essentially no CO_2. The gas around the tongue, having undergone gas exchange during the preceding breath, has about 14% O_2 and 5% CO_2. Consequently, during forward motion of this tongue toward the alveoli, O_2 will diffuse from the tongue to its surrounding gas while CO_2 will diffuse in the opposite direction. This is called Taylor dispersion[4] and it reduces the forward transport of O_2 produced by the onward convective movement of the tongue. This effect however is considered quite small and is generally not of significance to overall gas exchange.

   Note that if inspiration occurs at high rates as in exercise, such laminar flow may not occur in the larger airways—it may be turbulent and then Taylor dispersion is essentially noncontributory, as the turbulent mixing evens gas concentrations across the airway lumen.

3. Figure 14-2 shows the exponential increase in airway cross-sectional surface area as one proceeds deeper and deeper into the lungs. The significance of this curve is that since the mass flow rate of inspired gas is the same at every generation (because the airways are simply a conducting system), the forward velocity of O_2 molecules falls (since flow rate is the product of velocity and cross-sectional area). As it happens, by about generations 17 to 19, where the alveoli are just beginning to appear, this forward velocity has become so low that passage of O_2 from here on out to the alveoli is heavily dependent on simple gaseous diffusion, not just on continuing convective flow.
4. If alveoli are not equally ventilated with gas (and equally perfused with blood), their alveolar O_2 concentration will differ, as explained later in this chapter. Because adjacent alveoli are

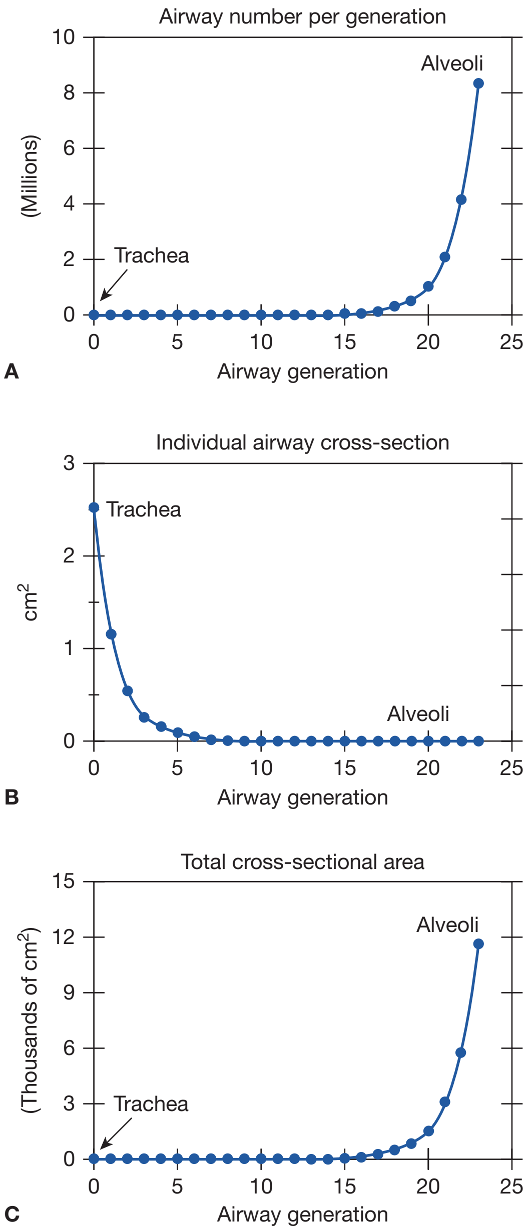

Figure 14-2 Relationship between number (**A**) and cross-sectional area (**B**) of the airways at a given generation. Note that total airway cross-sectional area (**C**) increases extremely rapidly beyond airway generation 15 or so, the beginning of the respiratory zone for gas exchange.

so physically close, there can be considerable diffusion of O_2 between such alveoli when their O_2 levels are different. This passive process tends to reduce concentration differences between these alveoli. However, although it can be detected experimentally, it is of probably minor clinical significance. Step 3 (and to some extent, Step 4) are responsible for most of the alveolar gas mixing that must occur for gas exchange to take place—that is, the mixing of each breath of newly inspired gas with alveolar gas still present from prior breaths.

5. The heart acts as a massaging pump to further enhance gas mixing into the alveolar gas spaces. Alternate filling and emptying of the cardiac chambers respectively facilitate exhaling and inhaling of airway gas into those alveoli physically close to the heart,[5] but have little effect on more distant alveoli. Although a well-known and easily demonstrated phenomenon, this so-called cardiogenic mixing is probably also of minimal physiologic impact for gas exchange.

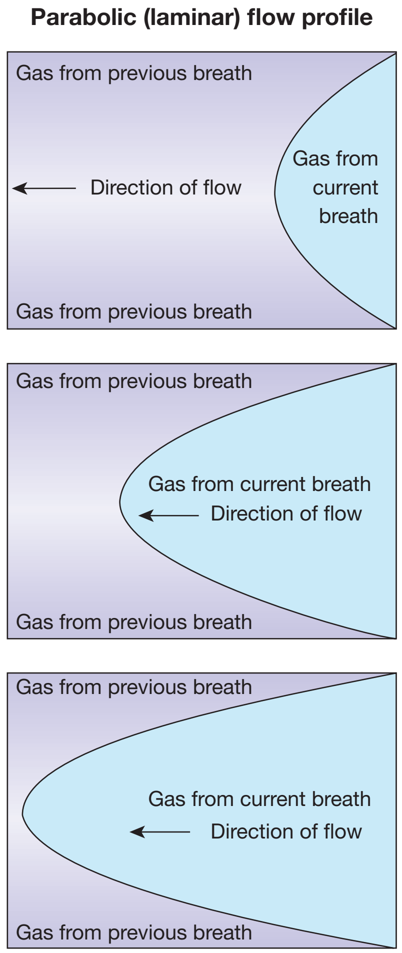

Figure 14-3 The parabolic profile of laminar flow. The three panels indicate sequential points in time during a single inspiration proceeding from right to left. Because the gas remaining from the previous breath has a low oxygen concentration and high CO_2 concentration relative to that of the inspired gas in the current breath, there will be diffusive exchange between the parabolic tongue and the surrounding gas (Taylor dispersion).

6. Once the dominant convective and diffusive gas transport steps have brought O_2 from the lips to the alveolar gas spaces, O_2 physically dissolves in the tissues separating alveolar gas from capillary blood, the blood–gas barrier (Fig. 14-1). O_2 then moves by diffusion through the blood–gas barrier and into the plasma. Over 98% of these O_2 molecules diffuse further, that is, into the red cell interior, and then bind rapidly to hemoglobin. The remaining 2% or so remain physically dissolved in the plasma and red cell water.

   This transport process from alveolar gas to hemoglobin is accomplished passively by simple diffusion: No convective forces or active transport processes are involved. The diffusion process is discussed more fully in Chapter 16. In normal lungs at rest, this process is very rapid and causes no O_2 transport limitation.

7. Finally, the red cells are transported convectively by cardiac pumping action out of the pulmonary capillaries and into the pulmonary veins and then to the left atrium, and left ventricle, finally reaching the various body tissues.

POTENTIAL DISRUPTIONS OF THE GAS TRANSPORT PATHWAY

If all the above elements of the transport pathway mentioned previously were functionally perfect, the partial pressure of O_2 (and other gases) would be identical in the gas of all 500 million alveoli and equal to that in systemic arterial blood. The system comes close to perfection in health,[6] but there is never complete equivalence of alveolar and arterial pressures, even in healthy young, normal people. Aging further leads to a progressive impairment of the pathway, with arterial P_{O_2} falling from 95 to 100 mm Hg at age 20 to 75 to 80 mm Hg at age 80 or thereabouts.[7] However, alveolar P_{O_2} tends to be invariant with age. Thus, the difference between alveolar and arterial P_{O_2} steadily increases from about 5 to 10 mm Hg to about 20 to 25 mm Hg over this age range. Pulmonary diseases such as asthma, emphysema and bronchitis, fibrosis, pneumonia, and many others can greatly disrupt gas transport to the point of causing death from insufficient tissue O_2 supply.

Consequently, it is essential to have a good understanding of the O_2 transport pathway and what may affect it even in health, in order to appreciate the problems seen in pulmonary diseases.

A traditional view of how to consider abnormalities of the transport pathway has evolved over the years and is very useful as a framework for discussion. It is based upon the end result of gas exchange—the arterial P_{O_2}—and there are different reasons why this variable can fall below normal values.

Four principal potential mechanisms of failure of the O_2 transport pathway can lead to a reduced arterial P_{O_2} (i.e., to arterial hypoxemia): (1) hypoventilation, (2) diffusion limitation, (3) shunt, and (4) ventilation–perfusion ($\dot{V}_A/\dot{Q}$) inequality. These are the so-called "intrapulmonary" factors that directly cause hypoxemia. Modulating "extrapulmonary" factors also are important. These include changes in inspired O_2 concentration, in total cardiac output, in overall metabolic rate, and in Hb concentration. The four "intrapulmonary" factors are now defined and discussed.

Hypoventilation

Normal levels of ventilation produce a tightly regulated arterial P_{CO_2} at 40 ± 2 mm Hg in normal subjects with several control systems in place to ensure this (for details, see Chapter 11). However, if overall ventilation is reduced for any reason, alveolar P_{CO_2} ($P_{A_{CO_2}}$), and therefore arterial P_{CO_2}, must rise to maintain constant the elimination of metabolically produced CO_2. Reciprocally, alveolar P_{O_2} ($P_{A_{O_2}}$), and hence arterial P_{O_2}, will fall (and by relatively similar amounts as P_{CO_2} will rise). The alveolar gas equation[8] quantitatively relates $P_{A_{O_2}}$ and $P_{A_{CO_2}}$, and is used to calculate how much $P_{A_{O_2}}$ will change for a change in $P_{A_{CO_2}}$:

$$P_{A_{O_2}} = P_{I_{O_2}} - \frac{Pa_{CO_2}}{R} + P_{A_{CO_2}} \cdot F_{I_{O_2}} \cdot \frac{(1 - R)}{R} \tag{1}$$

$P_{I_{O_2}}$ and $F_{I_{O_2}}$ are inspired O_2 partial pressure and fractional concentration, respectively, and R is the respiratory exchange ratio, normally 0.8.

Hypoventilation represents a failure of step 1 of the gas transport pathway (see above) and can occur for several reasons: (1) the control centers in the nervous system that regulate ventilation could malfunction due to trauma, diseases, drugs, or anesthetics; (2) there could be neuronal or neuromuscular dysfunction of the nerves supplying the chest wall muscles of respiration; (3) the chest wall muscles could be fatigued, damaged, or paralyzed; or (4) the airways or chest wall could be disrupted from trauma or other mechanical derangement such as compression, or in the case of airways, obstruction.

Conceptually this type of problem is usually thought of as a whole-lung issue, usually with obvious causes, and can be reversed by recognizing the cause and taking appropriate reparative and/or ventilatory supportive steps.

Diffusion Limitation

Whereas diffusive transport plays a recognizable, if small, role within the airways and alveolar gas (see above), the concept of diffusive limitation affecting arterial P_{O_2} is more usually associated with transport step 6—diffusion of O_2 from alveolar gas into the capillary and red cell.

This topic is specifically the focus of Chapter 16 and is not dealt with here. Indeed, the ensuing discussion of other factors sets aside diffusion limitation of O_2 transport for the sake of simplicity and assumes that the diffusive exchange of O_2 (and CO_2) between alveolar gas and capillary blood proceeds to completion within a single red cell's passage through the pulmonary microcirculation. This is reasonable under most conditions. Diffusion limitation in health is seen at sea level in some but not all athletes,[9] but only at or near maximal exercise. It is universally seen in normal subjects exercising at altitude.[10,11]

Shunt

A shunt is a blood pathway that does not allow any contact between alveolar gas and red cells, so that no gas exchange occurs in the affected region. Consequently, blood passes through a shunt maintaining a mixed venous blood composition. When this blood reaches pulmonary veins, the left atrium, and eventually arterial blood, it mixes with other blood that has undergone alveolar gas exchange. The result is a fall in arterial P_{O_2} and potentially an increase in arterial P_{CO_2}. (Arterial P_{CO_2} may not increase if the patient raises his or her level of ventilation, but hypoxemia will persist.)

Classic pathophysiologic scenarios giving rise to shunts are: (1) pulmonary edema, which fills alveoli with fluid, thereby abolishing their ventilation and any gas exchange; (2) alveolar filling with cellular and micro-organismal debris as in pneumonia, with the same result as in edema; (3) collapse of a region of lung due to pneumothorax, gas absorption distal to a fully obstructed airway, or external compression; (4) rarely, the presence of abnormal arteriovenous vascular channels in the lungs, that can occur in, for example, hepatic cirrhosis; and (5) direct right-to-left vascular communications at the level of the heart or great (extrapulmonary) blood vessels.

Ventilation–Perfusion ($\dot{V}_A/\dot{Q}$) Inequality

The exquisite and complex branching architecture of the airways and of the blood vessels makes the lungs very susceptible to the potential problem of nonuniform distribution of alveolar ventilation and of pulmonary blood flow. Whenever alveoli are ventilated at less than average rates, for example if their feeding airways become partially obstructed for any reason, the ratio of ventilation to blood flow ($\dot{V}_A/\dot{Q}$ ratio) will fall (assuming their blood flow does not fall similarly). In certain other conditions, lung regions may suffer a reduction in local blood flow rather than ventilation, so that the $\dot{V}_A/\dot{Q}$ ratio rises above the average value in those areas.

Whenever there is a range of $\dot{V}_A/\dot{Q}$ ratios in a lung such that the $\dot{V}_A/\dot{Q}$ ratio is not identical everywhere, it is said that $\dot{V}_A/\dot{Q}$ inequality exists. The pathologic cause of $\dot{V}_A/\dot{Q}$ inequality does not matter in this definition, nor whether the problem originates in the airways or blood vessels. The principal concept is that, compared with a lung having the same total alveolar ventilation and blood flow, a lung that has $\dot{V}_A/\dot{Q}$ inequality will exchange (all) gases in an inefficient manner.[12] The result is hypoxemia and, potentially, hypercapnia (raised arterial P_{CO_2}). A large section of this chapter presents the physiologic reasons for this effect of $\dot{V}_A/\dot{Q}$ inequality.

Understanding of $\dot{V}_A/\dot{Q}$ inequality can be demanding, but no matter what its pathologic origins, the concepts are similar. $\dot{V}_A/\dot{Q}$ inequality can occur at many different scales. Not uncommonly, it can manifest on a large scale as differences between the right and left lungs. Classic examples of this include unilateral atelectasis, pneumothorax, pulmonary embolus, or pneumonia. All these are relatively common phenomena that can lead to severe gas exchange disturbances. At the other end of the scale, there can be $\dot{V}_A/\dot{Q}$ ratio differences between essentially adjacent alveoli. However, research has shown that small groups of contiguous alveoli can maintain functional homogeneity of $\dot{V}_A/\dot{Q}$ ratios via rapid gas diffusion rates, possibly augmented by collateral ventilation and/or blood flow.[13] It is likely that all alveoli distal to individual respiratory (or perhaps terminal) bronchioles can retain functional homogeneity for gas exchange through these mechanisms.[14]

In between these two extremes of scale, vascular or airway obstruction at all levels will produce $\dot{V}_A/\dot{Q}$ inequality that, depending on how widespread it is, causes hypoxemia and potentially hypercapnia.

Even the young normal lung usually contains $\dot{V}_A/\dot{Q}$ inequality, which explains the 5– to 10–mm Hg P_{O_2} difference between alveolar gas and arterial blood generally observed in healthy young subjects.[15] There are several mechanisms for the existence of such $\dot{V}_A/\dot{Q}$ inequality.

Gravity-Based Inequality

Ventilation, and, even more so, blood flow are unevenly distributed in a manner systematically influenced by gravity.[6,16] This is due respectively to the weight of the lungs and of the blood in the blood vessels. Thus, dependent lung regions receive far more blood flow than nondependent regions, a finding that is in concept independent of body position. It turns out that the gravitational gradient in blood flow considerably exceeds that of ventilation. As a result, the nondependent lung regions are of higher than average $\dot{V}_A/\dot{Q}$ ratio, and the dependent regions are of lower than average $\dot{V}_A/\dot{Q}$ ratio.[6] Average $\dot{V}_A/\dot{Q}$ ratio is about 1.0, because total alveolar ventilation and blood flow are similar. At the apex of the upright human lung, the $\dot{V}_A/\dot{Q}$ ratio is about 3; at the base it is about 0.6, 5-fold lower. There is a smooth gradation between the two extremes as depicted in Fig. 14-4. This large-scale apex-to-base gradient in $\dot{V}_A/\dot{Q}$ ratios does not produce more than about a 4 mm Hg drop in arterial P_{O_2} (compared with expectations in the absence of this phenomenon), and thus a 4 mm Hg alveolar–arterial P_{O_2} difference.[6]

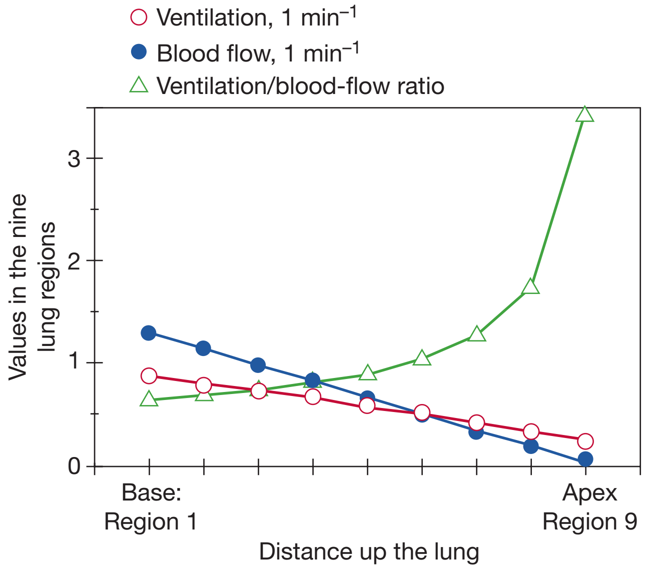

Figure 14-4 Topographic relationships between ventilation and blood flow as a function of distance up and down the upright lung (divided into nine contiguous regions). Although both ventilation and blood flow are higher at the base than at the apex, the ventilation–perfusion ratio ($\dot{V}_A/\dot{Q}$) rises exponentially from the bottom to the top of the lung. *(Adapted with permission from West JB. Ventilation/blood flow and gas exchange, 5th ed. Chicago, IL. Blackwell Scientific Publications; 1990.)*

Fractally Based $\dot{V}_A/\dot{Q}$ Inequality

The branching airway and blood vessel structure of the lung constitutes a fractal system that is innately susceptible to $\dot{V}_A/\dot{Q}$ inequality independent of gravity.[17] A fractal system is one in which the geometric pattern (e.g., of airway branching) is repeated at ever smaller scales. In the case of the airway tree it means in essence that the division of an airway into two "daughter" branches is a repeating feature from the large to the small airways. With some 23 sequential orders of branching, very small random inequalities in gas or blood flow distribution repeated at each branch point of the system can rapidly escalate into very significant degrees of nonuniform ventilation or blood flow. To illustrate, consider a branching system of just 16 dichotomous sequences—at each of the 16 branch points, air is not precisely split 50/50 between each daughter pair. Rather, suppose a 49%/51% split—a nonuniform effect of trivial proportions at any one airway branch. The most poorly ventilated regions (receiving 49% of the split at every one of the 16 branchings) end up with only about half as much ventilation as the best-ventilated regions that receive 51% of the split at each branch.

Unless the fractal structure somehow distributes both ventilation and blood flow in a correlated manner to preserve $\dot{V}_A/\dot{Q}$ ratios (even as $\dot{V}_A$ or $\dot{Q}$ individually vary), significant hypoxemia could result. Understanding the consequences of the fractal nature of the lung is a topic of much current interest. It appears that there must be correlation of $\dot{V}_A$ with $\dot{Q}$ since the large potential for fractally based hypoxemia is not generally realized.

Longitudinally Based Inequality

As airways and blood vessels progressively narrow with each branch point, resistance to gas and blood flow increases. Not all alveoli receive gas or blood from airways that have gone through the exact same number of branchings. Hence, some alveoli will be more, and some will be less, distant from the mouth. Such simple principles suggest the possibility of reduced $\dot{V}_A$ and/or $\dot{Q}$ of those alveoli further from the mouth compared to more proximal alveoli, and therefore the chance of a central to peripheral, or longitudinal, gradient in ventilation and blood flow. Although not universally observed, there is a fair amount of evidence that such inequality exists,[18] but its contribution to gas exchange is hard to establish. To the extent that similar physical principles apply to both gas and blood flow in the present context, one can theorize that more distant alveoli have both less ventilation and blood flow, so that again there is a natural tendency to preserve the $\dot{V}_A/\dot{Q}$ ratio between central and peripheral regions.

Anatomically Based Inequality

Another potential reason for nonuniform gas or blood flow distribution is intrinsic anatomic differences between lung regions. Perhaps the best example is in the dog and horse where, independent of body position in relation to gravity, the dorsal regions of the lower lobes often can be shown to have an unduly high share of total pulmonary perfusion. This tendency, presumably based on the overall branching architectural differences between lobes or within lobes, becomes important in concept when patients are moved from one body position to another, in order to best understand consequent changes in gas exchange.[19]

■ Collateral Ventilation and Blood Flow

To this point, a picture has been painted of a branching architecture that has no lateral connections between either adjacent airways or blood vessels at any level of branching. Such lateral connections can exist at several airway levels from large airways down to alveoli.[13,20] This is a species-dependent phenomenon, so that while the pig has little or no such collateral pathway structures, the dog has extensive collateral ventilatory channels. Humans are somewhere between these extremes.

Whatever the evolutionary pressure for collateral channel development, the ability to move gas around obstructions in airways by the use of collateral channels appears to be a useful property of human lungs. This is because total airway obstruction in the absence of collateral channels often leads to rapid alveolar gas absorption into the blood from the alveoli distal to the obstructed airway, and this in turn leads to atelectasis and therefore vascular shunts and hypoxemia. Remarkably, chronic human lung diseases typified by airway obstruction—chronic obstructive pulmonary disease (COPD), asthma—produce $\dot{V}_A/\dot{Q}$ inequality due to presence of poorly ventilated areas, but only uncommonly lead to true shunts.[21,22] The likely explanation for the paucity of shunts in COPD and asthma is the existence of collateral ventilation.

Collateral ventilation in humans therefore appears to be a naturally occurring structural phenomenon that can to some extent counteract the gas exchange consequences of diseases.

Collateral perfusion must also occur in the alveolar capillary network. This is deduced simply from the richly interconnecting microvascular network that has the potential to allow blood to flow easily around microvascular obstructions into adjacent vessels. Just how much collateral blood flow potential exists at a larger scale is not clear, being difficult to study. However, well-documented connections occur between the bronchial and pulmonary circulations,[23] creating a different kind of collateral circulatory network. The importance of this connection is evident when the pulmonary artery is either absent or embolized. Then, the bronchial circulation expands considerably and can support function of the affected lung regions long term.

■ Reactive Vasoconstriction and Bronchoconstriction

The distribution of ventilation or blood flow in the lung can be modified by vasoreactive or bronchoreactive functional changes that appear triggered by changes in alveolar gas composition. The most well-documented phenomenon is that of hypoxic pulmonary vasoconstriction.[24,25] Here, in response to local alveolar hypoxia produced by locally reduced ventilation, local pulmonary arterial constriction reduces blood flow in the hypoxic region. Whether this system developed to counteract disease or to cope with intrauterine life and the abrupt transition to air-breathing is arguable, although most people favor the latter explanation.

Irrespective of the reasons, the effect of hypoxic vasoconstriction is to help return the local ratio of ventilation to blood flow towards normal. This automatic effect (mediated by O_2-sensitive potassium channels in pulmonary arterial smooth muscle cells) is rarely able to fully restore $\dot{V}_A/\dot{Q}$ ratios to normal, but even partial improvements in $\dot{V}_A/\dot{Q}$ ratio facilitate gas exchange significantly. The negative aspect of hypoxic vasoconstriction is a rise in pulmonary vascular resistance. If this is substantial and protracted over time, pulmonary arterial hypertension can develop, eventually leading to right heart failure. However, factors other than hypoxic vasoconstriction are then also generally present—microvascular destruction and alveolar distortion—and these may be more important to heart failure than hypoxia per se. However, hypoxic vasoconstriction has provided a rationale for enriched O_2 therapy in patients with chronic disease to reduce the severity, or to delay the progression, of pulmonary hypertension.

To a much less obvious extent, a counterpart to hypoxic vasoconstriction occurs in the airways: hypocapnic bronchoconstriction.[26] Here, especially when pulmonary embolism occurs, the $\dot{V}_A/\dot{Q}$ ratio in the embolized area rises due to loss of blood flow from vascular obstruction. This increase in $\dot{V}_A/\dot{Q}$ ratio leads to a lower local P_{CO_2} (see below), which causes bronchoconstriction in the local area. This reduces local ventilation and thus tends to normalize the local $\dot{V}_A/\dot{Q}$ ratio. Radioactive tracer ventilation scans may show evidence of this as a modest reduction in the ventilation of embolized regions.

THE $\dot{V}_A/\dot{Q}$ RATIO AND GAS EXCHANGE

To this point, much space has been given to the concepts underlying the distribution of ventilation ($\dot{V}_A$), blood flow ($\dot{Q}$), and hence their ratio, $\dot{V}_A/\dot{Q}$. The reason for this lies in the importance of $\dot{V}_A/\dot{Q}$ ratios to the basic function of the lung—to exchange O_2 and CO_2 between the blood and the air. $\dot{V}_A/\dot{Q}$ inequality, no matter what its physiologic basis or pathologic cause, interferes with gas exchange and causes hypoxemia and sometimes hypercapnia.

The following section will explain the relationship of $\dot{V}_A/\dot{Q}$ inequality to gas exchange. The subject is complex and must be considered at several "concentric" levels. To start, we will consider how the $\dot{V}_A/\dot{Q}$ ratio in a small local lung region controls local P_{O_2} and P_{CO_2}, and therefore how much O_2 and CO_2 are exchanged in that region. This isolated approach requires at first some key assumptions. Removing the restrictions of these assumptions is the next "concentric" step in understanding $\dot{V}_A/\dot{Q}$ relationships. A final outer shell of modifying factors that can further affect gas exchange forms a third level of the analysis.

■ The $\dot{V}_A/\dot{Q}$ Ratio of a Small Homogeneous Unit of Lung and Gas Exchange

How the $\dot{V}_A/\dot{Q}$ ratio determines gas exchange is best explained by considering the flux of O_2 from the environment into and out of the alveolus with each breath as well as from the alveolar gas into the capillary blood. Equations that describe these processes and follow the fundamental principle of mass conservation must be used. Original descriptions of these appeared more than 70 years ago.[8,27–30] Figure 14-5 provides a model of the lung and specifies the total ventilation ($\dot{V}_A$) and blood flow ($\dot{Q}$) of this model together with the key locations of the relevant O_2 levels. It can be used to consider a small homogeneous unit of lung.

Convention has long considered ventilation over a period of time as a constant in spite of the tidal nature of breathing. This is in fact a very reasonable approximation that has stood the test of time. Similarly, blood flow is considered constant, and this too has proved reasonable. If $\dot{V}_A$ and $\dot{Q}$ are therefore considered as alveolar minute ventilation and blood flow of a small homogeneous unit respectively, the following simple mass conservation equations can be written for O_2:

$$\dot{V}_{O_2} = \dot{V}_I \cdot F_{I_{O_2}} - V_A \cdot F_{A_{O_2}} \qquad (2)$$

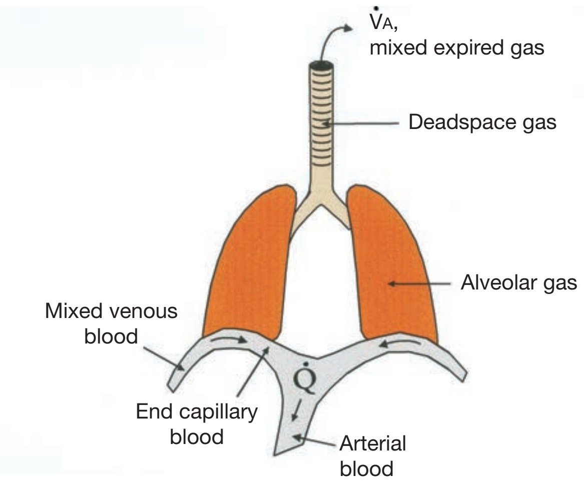

Figure 14-5 Conceptual model of the lungs indicating main sites in which oxygen and carbon dioxide partial pressures are different, together with the principal convective processes accomplishing gas exchange, ventilation ($\dot{V}_A$), and blood flow ($\dot{Q}$).

and

$$\dot{V}_{O_2} = Q \cdot Cc'_{O_2} - \dot{Q} \cdot C\bar{v}_{O_2} \qquad (3)$$

In these equations, $\dot{V}_{O_2}$ is amount of O_2 transferred from the environment into the blood per unit time and, given the assumption of steady state conditions, this, when summed over all such units in the lungs, equals metabolic rate. $\dot{V}\mathrm{I}$ and $\dot{V}\mathrm{A}$ are, respectively, the inspired and expired volumes of gas respired per minute, less the amount remaining in the conducting airways. As anticipated, $\dot{V}\mathrm{I}$ and $\dot{V}\mathrm{A}$ are close to being identical, otherwise the lungs would blow up or collapse in a short period of time. However, $\dot{V}\mathrm{I}$ does not generally equal $\dot{V}\mathrm{A}$ because slightly more O_2 is consumed per minute than is CO_2 produced (i.e., the respiratory quotient is in general not 1.0). Thus, $\dot{V}\mathrm{A} = \dot{V}\mathrm{I} - \dot{V}O_2 + \dot{V}_{CO_2}$. Mostly, the inequality of $\dot{V}\mathrm{I}$ and $\dot{V}\mathrm{A}$ can be ignored because the difference is only about 1%—if $\dot{V}\mathrm{I}$ is 6 L/min and $\dot{V}O_2$ is 300 mL/min with $\dot{V}_{CO_2}$ at 240 mL/min, $\dot{V}\mathrm{A} = 5.94$ L/min. Although this small difference is not ignored in research applications, it can be for the present purposes, so that $\dot{V}\mathrm{I}$ is replaced by $\dot{V}\mathrm{A}$ in Equation (2), simplifying the analysis. In Equation (2), $F\mathrm{I}_{O_2}$ and $F\mathrm{A}_{O_2}$ are the fractional concentrations (F) of O_2 in inspired (I) and exhaled alveolar (A) gas, respectively, from a small unit in Fig. 14-5. In Equation (3), Cc'_{O_2} and $C\bar{v}_{O_2}$ are the O_2 concentrations (C) in the oxygenated end capillary blood leaving (c′) and the deoxygenated blood entering ($\bar{v}$) the vasculature respectively. The abbreviation c′ stands for end capillary blood, and $\bar{v}$ for mixed venous (pulmonary arterial) blood.

Since Equations (2) and (3) both describe the same O_2 flux rate ($\dot{V}O_2$) they may be set equal to each other:

$$\dot{V}\mathrm{A}\,[F\mathrm{I}_{O_2} - F\mathrm{A}_{O_2}] = \dot{Q}\,[Cc'_{O_2} - C\bar{v}_{O_2}] \qquad (4)$$

and rearranged so that:

$$\dot{V}\mathrm{A}/\dot{Q} = [Cc'_{O_2} - C\bar{v}_{O_2}]/[F\mathrm{I}_{O_2} - \mathrm{A}_{O_2}] \qquad (5)$$

It should further be noted that because diffusion equilibration of O_2 transfer across the alveolar–capillary membrane is assumed to be complete, alveolar P_{O_2} and end capillary P_{O_2} are identical. Hence, the relationship between $F\mathrm{A}_{O_2}$ and Cc'_{O_2} is uniquely dictated by the O_2-Hb dissociation curve such that knowing $F\mathrm{A}_{O_2}$ allows us to determine directly Cc'_{O_2} (or vice versa).

Equation (5) is very revealing and explains directly the role of the $\dot{V}\mathrm{A}/\dot{Q}$ ratio in governing alveolar gas exchange. This equation states that for a given set of what may be called boundary conditions (i.e., composition of inspired gas and mixed venous blood, represented here by $F\mathrm{I}_{O_2}$ and $C\bar{v}_{O_2}$, respectively) and for a known O_2–Hb dissociation curve, alveolar (and thus end capillary) P_{O_2} is uniquely determined by the ratio of alveolar ventilation ($\dot{V}\mathrm{A}$) to blood flow ($\dot{Q}$).

Under the given assumptions, summarized as (1) continuous and constant ventilation and blood flow; (2) steady state conditions; (3) diffusion equilibration of alveolar–capillary exchange; and (4) equality of inspired and expired ventilation, equations identical in construct to Equation (5) can be written for any gas being exchanged by the lung.

For CO_2, this produces Equation (6):

$$\dot{V}\mathrm{A}/\dot{Q} = [C\bar{v}_{CO_2} - Cc'_{CO_2}]/[F\mathrm{A}_{CO_2} - F\mathrm{I}_{CO_2}] \qquad (6)$$

The order of bracketed terms on the right is reversed to maintain positive numbers, since CO_2 is being eliminated from the blood. Of course, $F\mathrm{I}_{CO_2}$ is essentially zero and thus drops out of the equation.

Unfortunately, neither Equation (5) nor (6) is amenable to simple quantitative solutions, because of the complexity of the O_2 and CO_2 dissociation curves. The equations are however readily explored by appropriate computerized numerical analyses.[31–35] Using such programs, one can explore the relationship between $\dot{V}\mathrm{A}/\dot{Q}$ ratio and alveolar P_{O_2} and P_{CO_2}, and this is done in Fig. 14-6. These relationships are important because they indicate what degrees of $\dot{V}\mathrm{A}/\dot{Q}$ abnormality are required to affect gas exchange for both O_2 and CO_2. The four panels of Fig. 14-6 show alveolar P_{O_2} and P_{CO_2} as well as end capillary O_2 and CO_2 concentrations. The latter better reflect total gas exchange as a function of $\dot{V}\mathrm{A}/\dot{Q}$ ratio. Specific conditions for Fig. 14-6 are that mixed venous blood P_{O_2} is 40 mm Hg and P_{CO_2} 45 mm Hg, normal resting values. Also, inspired gas is room air, and [Hb] is 15 g/dL. In each panel, the three solid circles are positioned at the normal $\dot{V}\mathrm{A}/\dot{Q}$ ratio (of about 1.0) and at $\dot{V}\mathrm{A}/\dot{Q}$ ratios 10 times greater and less. All four relationships are highly nonlinear. Focusing on the two lower panels, it is evident for O_2 that a 10-fold reduction in $\dot{V}\mathrm{A}/\dot{Q}$ greatly reduces local O_2 transport, whereas a 10-fold increase barely improves it. Furthermore, as $\dot{V}\mathrm{A}/\dot{Q}$ falls even lower than 0.1, there is little further loss in O_2 transport. There is however little protection against a fall in $\dot{V}\mathrm{A}/\dot{Q}$ below 1.0, because the curve is very steep below a $\dot{V}\mathrm{A}/\dot{Q}$ of 1.0, as the lower left panel shows. For CO_2, the curves are opposite in slope (P_{CO_2} falls as $\dot{V}\mathrm{A}/\dot{Q}$ increases). However, unlike the case for O_2, there is little difference between a $\dot{V}\mathrm{A}/\dot{Q}$ of 1.0 and a 10-fold reduction, whereas an increase in $\dot{V}\mathrm{A}/\dot{Q}$ considerably reduces alveolar P_{CO_2} and end capillary CO_2 concentration. The reason for the differences between O_2 and CO_2 lies mainly in the slopes of their dissociation curves: that for CO_2 is about 10-fold greater than that for O_2. It has been shown that the higher the slope of the dissociation curve (or equivalently for an anesthetic gas, its solubility) the more it is sensitive to areas of high $\dot{V}\mathrm{A}/\dot{Q}$. The lower the slope or solubility, the more the gas is affected by areas of low $\dot{V}\mathrm{A}/\dot{Q}$. Consequently, areas of low $\dot{V}\mathrm{A}/\dot{Q}$ predictably cause more reduction in arterial P_{O_2} than increase in arterial P_{CO_2}. Although Fig. 14-6 is true strictly only for the stated "boundary" conditions (i.e., mixed venous blood and inspired gas

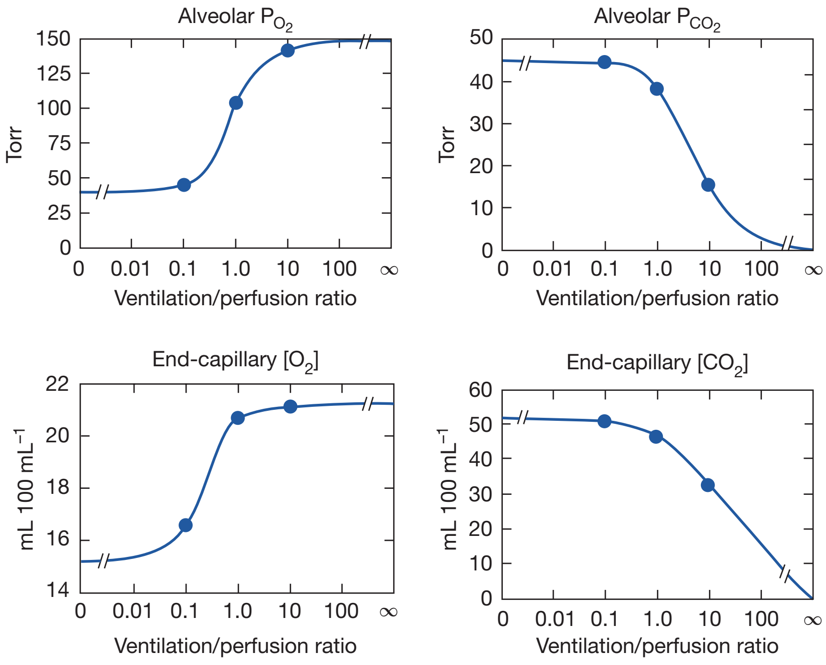

Figure 14-6 Calculated relationships between alveolar P_{O_2} and P_{CO_2} and the ventilation–perfusion ratio (*top panels*) and their corresponding end-capillary blood concentrations (*lower panels*). The three solid circles in each case represent values for ventilation–perfusion ratios of 0.1, 1.0, and 10. (See text for further details.)

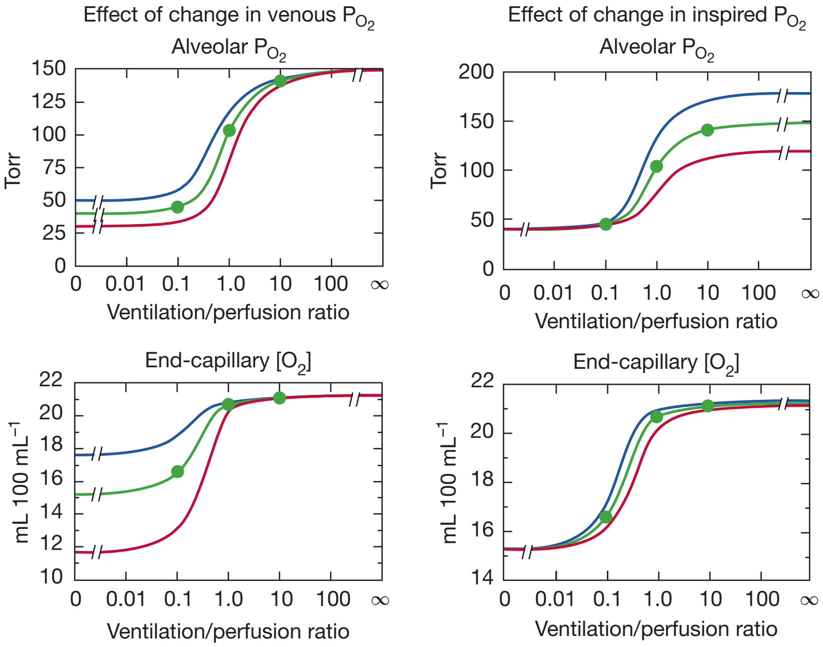

Figure 14-7 Effects of changes in mixed venous P_{O_2} (*left panels*) or inspired P_{O_2} (*right panels*) on alveolar P_{O_2} and associated end-capillary oxygen concentrations. Note that changes in venous P_{O_2} mostly affect values associated with low ventilation–perfusion ratios, whereas changes in inspired P_{O_2} affect units throughout the $\dot{V}_A/\dot{Q}$ range, especially those with medium to high $\dot{V}_A/\dot{Q}$ ratios.

composition), the principles hold even for different such conditions, as shown in Fig. 14-7 for O_2. The left panels illustrate how changes in mixed venous P_{O_2} alone will affect alveolar P_{O_2} and end capillary $[O_2]$ via Equation (4). The right panels correspondingly show how change in inspired P_{O_2} affects O_2. Venous P_{O_2} is selected at 30, 40, and 50 mm Hg, and inspired P_{O_2} is chosen to be 120, 150, and 180 mm Hg. Changes in venous P_{O_2} dramatically affect P_{O_2} and $[O_2]$ in unventilated and poorly ventilated regions as well as regions approaching normal but have no real effect on high $\dot{V}_A/\dot{Q}$ alveoli. Altering inspired P_{O_2} (but not venous) has the converse effect if P_{O_2} is examined (top right panel), but, due to the nonlinear shape of the O_2–Hb dissociation curve, effects on $[O_2]$ are minimal in high $\dot{V}_A/\dot{Q}$ areas, small in very low $\dot{V}_A/\dot{Q}$ areas, and more significant between $\dot{V}_A/\dot{Q}$ ratios of 0.1 and 1.0 (bottom right panel). This figure shows how the inspired and mixed venous "boundary conditions" alter the magnitude (but not basic patterns) of alveolar gas exchange.

If one returns to the normal boundary conditions ($P\bar{v}_{O_2} = 40$ mm Hg, $PI_{O_2} = 150$ mm Hg), one can explore the consequences of $\dot{V}_A/\dot{Q}$ inequality on gas exchange. In reality, the complex structure of the lungs defies a simple analysis but conceptually even a two-compartment model is an invaluable aid to understanding this conceptually difficult area.

Figure 14-8 shows such a simple two-compartment model in three configurations: (1) each compartment equally ventilated and perfused such that there is no $\dot{V}_A/\dot{Q}$ inequality; (2) the left compartment hypoventilated due to airway obstruction, causing $\dot{V}_A/\dot{Q}$ inequality; and (3) the left compartment hypoperfused from vascular obstruction. Table 14-1 shows the corresponding O_2 and CO_2 calculations for each compartment. Specific assumptions common to all three models are the mixed venous P_{O_2} remains at 40 mm Hg; inspired P_{O_2} is constant at 150 mm Hg; total alveolar ventilation summed over both compartments is constant as is total blood flow, both taken to be 6 L/min; [Hb] is constant at 15 g/dL. Further, airway obstruction reduces L-hand compartmental ventilation from 3.0 to 0.3 L/min, redistributing the balance to the R-hand compartment. Vascular obstruction is of the same order as the right panel of the figure shows. Note that for both obstructive models, one compartment has developed a $\dot{V}_A/\dot{Q}$ ratio less than average and the other a $\dot{V}_A/\dot{Q}$ ratio greater than average, irrespective of the location of the obstruction.

Using the curves of Fig. 14-6, for $P\bar{v}_{O_2} = 40$ mm Hg and $PI_{O_2} = 150$ mm Hg, $P\bar{v}_{CO_2} = 45$ mm Hg and $PI_{CO_2} = 0$ mm Hg, alveolar P_{O_2} and P_{CO_2} are listed for each compartment of Fig. 14-8 in Table 14-1.

In Table 14-1, alveolar diffusion equilibration is assumed to be complete such that alveolar P_{O_2} (PA_{O_2}) equals end capillary P_{O_2} (Pc'_{O_2}); the same holds for P_{CO_2}. In each obstructive model, the low $\dot{V}_A/\dot{Q}$ compartment has a lower-than-average P_{O_2} and higher-than-average P_{CO_2} as Fig. 14-6 dictates. The converse is seen for the compartment of high $\dot{V}_A/\dot{Q}$ ratio. Corresponding end capillary O_2 and CO_2 concentrations also are listed in Table 14-1.

The question is what will the mixed arterial blood and mixed expired gas O_2 and CO_2 levels change to as a result of obstruction of one compartment, and how will this affect the ability of the total system to exchange O_2 and CO_2? To answer these questions, one applies

simple mixing questions to the two individual compartments (left [L] and right [R]):

For O_2:

$$P\bar{A}_{O_2} = (PA_{O_{2L}} \cdot \dot{V}A_L + PA_{O_{2R}} \cdot \dot{V}A_R)/(\dot{V}A_L + \dot{V}A_R)$$

$$Ca_{O_2} = (Cc'_{O_{2L}} \cdot \dot{Q}_L + Cc'_{O_{2R}} \cdot \dot{Q}_R)/(\dot{Q}_L + \dot{Q}_R) \qquad (7)$$

For CO_2, identical equations apply. These mixing equations conserve mass and use the principle that the two gas or blood streams combine in a manner proportional to their relative ventilation and blood flow, respectively. Table 14-1 lists the results of these calculations, giving mixed alveolar partial pressure ($P\bar{A}_{O_2}$, $P\bar{A}_{CO_2}$) and mixed arterial concentrations (Ca_{O_2}, Ca_{CO_2}). From the blood–gas concentration, corresponding arterial partial pressures (Pa_{O_2}, Pa_{CO_2}) are read directly off the O_2 and CO_2 dissociation curves. Finally, whole-lung computations of O_2 and CO_2 exchange rates (mL/min) are determined using either Equation (2) or (3) and the mixed alveolar or arterial data respectively, and the mixed alveolar to arterial partial pressure differences expressed for each gas.

The results are very instructive. Both obstructive models result in hypoxemia and slight hypercapnia, but the effects on arterial P_{O_2} and on the alveolar–arterial P_{O_2} difference greatly exceed those for CO_2 due to both shape and slope differences between the dissociation curves of the two gases. Airway obstruction produces more hypoxemia but *less* hypercapnia than the identical degree of vascular obstruction. This reflects the 10-fold greater dissociation curve slope of CO_2 compared to O_2, rendering O_2 relatively more susceptible to the lower $\dot{V}A/\dot{Q}$ areas seen in the airway obstruction model (0.1 vs. 0.5) (Fig. 14-8) and CO_2 relatively more susceptible to the higher $\dot{V}A/\dot{Q}$ areas of vascular obstruction (10.0 vs. 1.9) (Fig. 14-8) as Fig. 14-6 would predict.

Both models have impaired overall O_2 and CO_2 exchange (recall that venous blood, inspired gas, total ventilation, and blood flow were all considered fixed and identical for all three models) as a result of the development of $\dot{V}A/\dot{Q}$ mismatch. In keeping with the differential sensitivity of O_2 and CO_2 to regions of low and high $\dot{V}A/\dot{Q}$ discussed earlier, total O_2 transport is diminished to a greater extent in the airway obstruction model than in the vascular obstruction model (Table 14-1). The converse is true for CO_2, also shown in Table 14-1.

The principal effects of $\dot{V}A/\dot{Q}$ inequality as they apply to O_2 and CO_2 exchange may thus be listed.

$\dot{V}A/\dot{Q}$ inequality:

a. Affects both gases, no matter what the pathologic basis of the inequality.
b. Causes arterial hypoxemia and hypercapnia.
c. Causes usually more severe hypoxemia than hypercapnia.
d. Affects O_2 more than CO_2 when very low $\dot{V}A/\dot{Q}$ regions develop.
e. Affects CO_2 more than O_2 when very high $\dot{V}A/\dot{Q}$ regions develop.
f. Impairs total O_2 and CO_2 exchange by the lung.
g. Creates alveolar–arterial differences for both gases.

COMPENSATION FOR THE EFFECTS OF $\dot{V}A/\dot{Q}$ MISMATCH

The preceding analysis shows that if no changes in total ventilation, blood flow, mixed venous blood, or inspired gas composition occur, O_2 and CO_2 transfer across the lung is compromised. This is not viable in the steady state: the lungs must find a way to restore total O_2 and CO_2 transfer to levels equal to metabolic use of O_2 and production of CO_2. This leads to the next concentric level of consideration of $\dot{V}A/\dot{Q}$ inequality referred to at the start of this section.

Here we ask what compensatory mechanisms exist to achieve restoration of O_2 and CO_2 transfer, assuming that the initial pathophysiologic insults have persisted unchanged. The same models as in Fig. 14-8 and Table 14-1 will be used.

■ Changes in Mixed Venous Blood

The only possible short-term compensatory changes are in mixed venous blood, total ventilation, and cardiac output. (Hb change in response to tissue hypoxia requires days to weeks to develop and then is by no means always observed; changing inspired P_{O_2} is not usually an option until the patient seeks medical attention.) To reduce complexity, changes in venous blood alone are first addressed.

If it is assumed that there is no limit to how much O_2 can be extracted from the arterial blood by the peripheral tissues, it is evident that $\dot{V}A/\dot{Q}$ inequality will passively lead to a reduced venous P_{O_2} and increased venous P_{CO_2}. This is deduced simply from the

TABLE 14-2 Gas Exchange Effects of Passive Changes in Mixed Venous Blood—Gas Values Required to Restore $\dot{V}O_2$ and $\dot{V}CO_2$ to Normal in the Models of Figure 14-8

	Airway Obstruction Model		Vascular Obstruction Model	
	Before Change	After Change	Before Change	After Change

$P\bar{v}_{CO_2}$, mm Hg	45.0	50.7	45.0	62.4
Pa_{O_2}, mm Hg	55	46	77	67
Pa_{CO_2}, mm Hg	39.0	44.5	40.9	55.6
$\dot{V}_{O_2}$, mL·min^{-1}	212.0	328 (normal)	294.0	328.0 (normal)
$\dot{V}_{CO_2}$, mL·min^{-1}	234.0	270 (normal)	203.0	270.0 (normal)

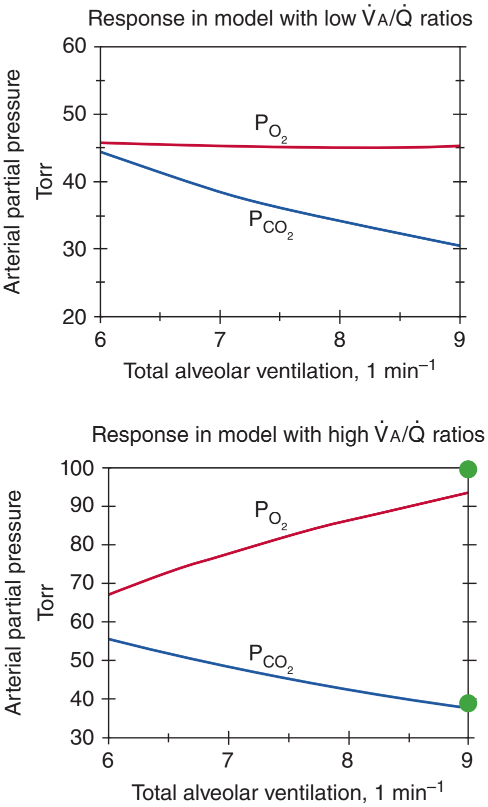

Figure 14-9 Effect of increasing alveolar ventilation on arterial P_{O_2} and P_{CO_2} in the two models with ventilation–perfusion inequalities in Figure 14-8. *Top panel* is that for Model 2 and *bottom panel* is that for Model 3. Increasing ventilation is ineffective in restoring arterial P_{O_2} in the low $\dot{V}\mathrm{A}/\dot{Q}$ Model 2, but much more effective in the high $\dot{V}\mathrm{A}/\dot{Q}$ Model 3. Both models respond in terms of P_{CO_2}.

hypoxemia and hypercapnia initially produced by the $\dot{V}\mathrm{A}/\dot{Q}$ insult, together with the need to extract the same amount of O_2 from (and add CO_2 to) each mL of blood perfusing the tissues as before the $\dot{V}\mathrm{A}/\dot{Q}$ insult developed.

If venous P_{O_2} falls (and P_{CO_2} rises), Fig. 14-7 indicates that alveolar P_{O_2} will fall in each $\dot{V}\mathrm{A}/\dot{Q}$ compartment (as will P_{CO_2} rise). Thus, a circle of events is set up such that if a single red cell were followed around the circulation, at each passage through the lungs and then tissues, P_{O_2} would fall progressively with each circuit of the body.

Although not intuitively obvious, this reduction in both arterial and venous P_{O_2} will not "bottom out" at zero (or in the case of CO_2 rise toward infinity) unless the $\dot{V}\mathrm{A}/\dot{Q}$ insult was fatally overwhelming in the first place. Both arterial and venous P_{O_2} will restabilize at new lower values (P_{CO_2} values will be higher) than were present immediately after the $\dot{V}\mathrm{A}/\dot{Q}$ insult developed. In so doing, $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ will have been restored to normal values.

To explore this quantitatively, we will continue on with the models of Fig. 14-8 and Table 14-1 to show just what changes in venous and arterial P_{O_2} and P_{CO_2} must occur as a result of this process in order to restore pulmonary O_2 and CO_2 exchange to normal. The values are shown in Table 14-2. For the airways obstruction model, the passive blood gas changes are greater for O_2 than CO_2, consonant with the greater initial decrement in O_2 exchange caused by airway obstruction in the first place. For the vascular obstruction model, the effects are more marked for CO_2, for corresponding reasons. To restore $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ in the airway obstruction model, hypoxemia is now more severe, but hypercapnia is mild. However, with vascular obstruction, hypoxemia remains mild while hypercapnia is severe. In both cases, the lung is meeting the original healthy requirement of transferring 328 and 270 mL/min of O_2 and CO_2, respectively.

The speed of passive venous blood composition changes is very rapid, taking place in seconds to minutes as the blood moves continuously around the vascular system between lungs and tissues. The principal effects of the changes can be summarized as follows:

a. Following development of $\dot{V}\mathrm{A}/\dot{Q}$ mismatch, and a fall in $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ at the lungs, mixed venous P_{O_2} will fall and mixed venous P_{CO_2} will rise to restore pulmonary $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ to equal the original metabolic requirements for O_2 and CO_2 transport.
b. As a result, there will always be a further fall in arterial P_{O2} and rise in arterial P_{CO_2}, compared to conditions prior to mixed venous blood changes.
c. When the $\dot{V}\mathrm{A}/\dot{Q}$ insult primarily involves development of extremely low $\dot{V}\mathrm{A}/\dot{Q}$ areas, those effects are more marked for O_2 than for CO_2.
d. When the $\dot{V}\mathrm{A}/\dot{Q}$ insult primarily consists of high $\dot{V}\mathrm{A}/\dot{Q}$ areas, CO_2 is affected more than O_2.

■ Changes in Total Ventilation

When either low or high $\dot{V}\mathrm{A}/\dot{Q}$ areas develop and the mixed venous and arterial adjustments occur as described earlier, there is hypoxemia and hypercapnia. Either or both may well stimulate an immediate increase in total ventilation,[36] which will alleviate to some extent both the hypoxemia and hypercapnia. Figure 14-9 shows for the same two examples used earlier how increases in alveolar ventilation (distributed in the same proportions as in each of the two $\dot{V}\mathrm{A}/\dot{Q}$ models of Fig. 14-8) variably improve arterial P_{O_2} and P_{CO_2}. In the low $\dot{V}\mathrm{A}/\dot{Q}$ (airways obstruction) model, a 50% increase in total alveolar ventilation from the normal value of 6 to 9 L/min drops arterial P_{CO_2} to almost 30 mm Hg, well below the normal standard value of 40 mm Hg. Arterial P_{O_2}, however, is not affected at all. This is because even a 50% increase in ventilation of the very poorly ventilated unit fails to significantly increase end capillary P_{O_2} of that unit (Fig. 14-6), whereas in the better ventilated unit of that model, Hb in the end capillary blood was already virtually fully saturated before the increase in ventilation.

For the model with vascular obstruction, a 50% increase in alveolar ventilation returns both P_{O_2} and P_{CO_2} to near-normal values (Fig. 14-9, lower panel). The difference in the two model responses

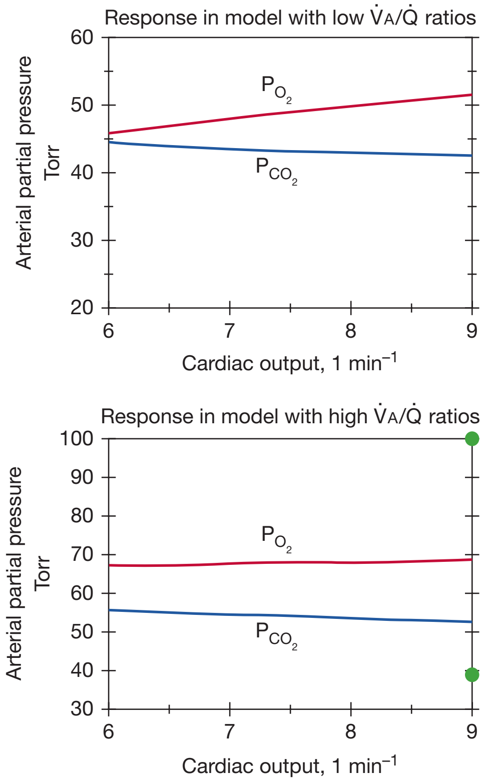

Figure 14-10 Effects of increases in cardiac output on arterial P_{O_2} and P_{CO_2} in Models 2 and 3 of Fig. 14-8. Cardiac output produces a significant rise in P_{O_2} in the presence of regions of very low ventilation–perfusion ratio (*top panel*) but has little influence in the presence of higher ventilation–perfusion ratios (*bottom panel*). P_{CO_2} is affected only minimally in either case.

to ventilation reflects the original $\dot{V}A/\dot{Q}$ ratios of the two compartments—that is, where they lie on the curves of Fig. 14-6.

Changes in Cardiac Output

One final compensatory adjustment is possible—an increase in cardiac output. Adrenergic stimulation by arterial hypoxemia can raise cardiac output by 50% or more, and this will also tend to improve arterial blood gases by raising mixed venous P_{O_2} (and lowering mixed venous P_{CO_2}). Figure 14-10 shows the effects on arterial P_{O_2} and P_{CO_2} of such increases, as was done for ventilation in Fig. 14-9, again assuming that the relative distribution of blood flow remains unaltered between the two compartments as total blood flow is increased. For a lung with airway obstruction causing very low $\dot{V}A/\dot{Q}$ regions (upper panel), an increase in cardiac output significantly improves arterial oxygenation—more so than does the same relative increase in ventilation. However, arterial P_{CO_2} is only slightly improved. In stark contrast, increases in cardiac output barely alter arterial P_{O_2} and P_{CO_2} in the high $\dot{V}A/\dot{Q}$ ratio model, especially when it is recalled (Fig. 14-9) how effective an increase in ventilation is in restoring arterial P_{O_2} and P_{CO_2}.

When both ventilation and cardiac output are simultaneously increased, there is no real synergistic effect (Fig. 14-11): P_{O_2} and P_{CO_2} are improved as predicted from the individual changes (i.e., as shown in Figs. 14-9 and 14-10).

In all the calculations depicted in Figs. 14-9 to 14-11, the two-compartment models are exchanging the necessary amounts of O_2 and CO_2 to sustain normal metabolism. Depending on (a) the ventilatory and cardiovascular responses to the original insult causing $\dot{V}A/\dot{Q}$ mismatch and (b) the fundamental pattern of $\dot{V}A/\dot{Q}$ mismatch (i.e., the preponderance of low and/or high $\dot{V}A/\dot{Q}$ areas), it is possible to observe hypercapnia, normocapnia, or hypocapnia. However, it is very uncommon for arterial P_{O_2} to be fully normalized by the compensatory mechanisms, and the observed degree of hypoxemia can be extremely variable. As an important clinical corollary, it becomes difficult to establish the severity of the $\dot{V}A/\dot{Q}$ insult per se when the extent of compensating mechanisms cannot be easily established, since these two aspects are so intertwined in their resulting effect on gas exchange.

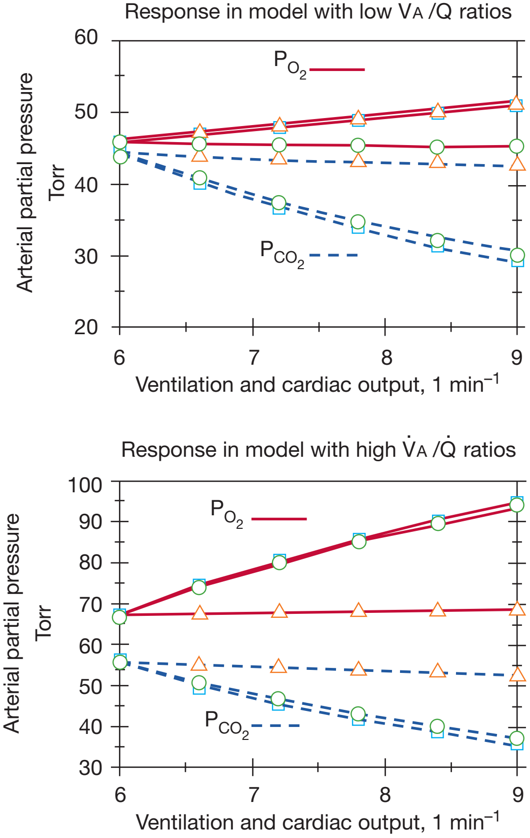

Figure 14-11 Responses to simultaneous increases in ventilation and cardiac output (compared with responses to individual increases as shown in Figs. 14-9 and 14-10). Simultaneous increases do not provide for significantly more improvement than with either alone. o-o, response to increased ventilation only; △—△, response to increased cardiac output only; □-□, response to simultaneously increased ventilation and cardiac output.

ASSESSMENT OF VENTILATION–PERFUSION INEQUALITY

Whereas the preceding discussion highlights the complexity of how $\dot{V}A/\dot{Q}$ inequality impairs gas exchange, there is a need for methods to assess the extent of such mismatch in the clinical setting. The multiple inert gas elimination technique was developed expressly for this purpose.[37,38] Although the technique provides the necessary descriptions of the extent and pattern of inequality, it remains a complex technique that is not well suited to routine clinical use. Several traditional quantifying indices of $\dot{V}A/\dot{Q}$ mismatch remain useful on a daily basis. They all make use of O_2 and CO_2 as indicator gases:

1. The first is the alveolar–arterial P_{O_2} difference, PA_{O_2}– Pa_{O_2}. This is the difference between alveolar P_{O_2} (PA_{O_2}, calculated from the alveolar gas equation presented subsequently) and the measured arterial P_{O_2} (PA_{O_2}). The PA_{O_2} − Pa_{O_2} is therefore given by

$$PI_{O_2} - Pa_{CO_2}/R + Pa_{CO_2} \cdot FI_{O_2} \cdot (1 - R)/R - Pa_{O_2} \qquad (8)$$

Use of this equation requires knowledge of inspired P_{O_2} and $[O_2]$, the respiratory exchange ratio R, and the ideal alveolar P_{CO_2}, which is the P_{CO_2} that would be observed in alveolar gas of a homogeneous lung having the R value of the patient's actual lung at the time. Three problems arise with the application of this equation: First, the result is very dependent on PI_{O_2} even when the amount of $\dot{V}A/\dot{Q}$ inequality does not change as PI_{O_2} is varied. Second, the value of R is generally not known and must be assumed. Suppose $P_{CO_2} = 40$ mm Hg and $Pa_{O_2} = 90$ mm Hg for a subject breathing sea level air. If R were 0.7, $PA_{O_2} - Pa_{O_2}$ would be 7 mm Hg (Equation 8). But if R were 1.0, $PA_{O_2} - Pa_{O_2}$ would be 20 mm Hg, a quite different value. Third, in some cases, the usual substitution for the ideal alveolar P_{CO_2}, the measured arterial P_{CO_2}, leads to a systematic error because arterial P_{CO_2} can be significantly higher than the ideal alveolar value. However, $PA_{O_2} - Pa_{O_2}$ remains a very useful index of $\dot{V}A/\dot{Q}$ inequality providing these limitations are kept in mind.

2. The second index is simply the ratio of arterial P_{O_2} to FI_{O_2}, which in a perfectly normal lung is virtually insensitive to PI_{O_2}, a major advantage. However, even that is an over-simplification, because this ratio may not be as constant as hoped for depending on the pattern of $\dot{V}A/\dot{Q}$ inequality present.
3. A third index is venous admixture (QSQT) or, equivalently, physiologic shunt. This is a parameter that expresses what magnitude shunt would have to be present in a particular case to explain a patient's arterial P_{O_2} if that shunt were the sole cause of hypoxemia. The formula is:

$$\%QsQ_T = 100 \cdot [Cc'_{O_2} - Ca_{O_2}]/[Cc'_{O_2} - C\bar{v}_{O_2}] \qquad (9)$$

   where Cc'_{O_2} is the calculated end capillary $[O_2]$ of blood perfusing a hypothetical alveolus exchanging gas at the overall respiratory exchange ratio of the patient's actual lungs. Ca_{O_2} is arterial and $C\bar{v}_{O_2}$ mixed venous $[O_2]$, respectively. This parameter, working in the O_2 concentration domain (rather than the partial pressure domain of the $PA_{O_2} - Pa_{O_2}$), better reflects the degree of the gas exchange defect but requires knowledge of the ideal alveolar conditions to calculate Cc'_{O_2}, as well as [Hb]. It also is sensitive to PI_{O_2} in that when $\dot{V}A/\dot{Q}$ inequality is present, its contribution to QsQT diminishes progressively as PI_{O_2} is raised. The most limiting aspect of this parameter however is the need to know the value of $C\bar{v}_{O_2}$, reflecting mixed venous blood. If this must be assumed rather than measured, the value of QsQT will be only as good as the assumption, which may be extremely misleading if changes in $C\bar{v}_{O_2}$ in fact occur but are not accounted for in the QsQT calculation.
4. Finally, as a fourth index, using the arterial and mixed expired partial pressures of CO_2 (Pa_{CO_2} and $P\bar{E}_{CO_2}$, respectively), a very similar calculation to QSQT can be performed to compute the percentage of total ventilation that is wasted on non-gas-exchanging ("deadspace") areas of the lungs. As for QsQT, the calculation determines the magnitude of the deadspace that would have to be present to dilute the alveolar P_{CO_2} down to the mixed expired level if that deadspace were the only abnormality in ventilation. Expressed as deadspace (VD)/tidal volume (VT) percentage,

$$\%V_D/V_T = 100 \cdot [Pa_{CO_2} - P\bar{E}_{CO_2}]/[Pa_{CO_2}] \qquad (10)$$

This parameter is independent of PI_{O_2} but is weakened by the fact that the normal airway conducting volume is included in the computed result. Thus, it may be difficult to separate how much the VD/VT value represents this normal anatomic deadspace as opposed to reflecting $\dot{V}A/\dot{Q}$ inequality amongst the alveoli. This problem is amplified because even normally VD/VT is very dependent on the size of the tidal volume even if the deadspace volume itself is essentially constant. Thus, for a deadspace volume of 150 mL and a tidal volume of 500 mL, VD/VT is 30%, but if tidal volume were to drop to 400 mL, VD/VT now becomes 38%—not because $\dot{V}A/\dot{Q}$ inequality has developed, but simply because smaller breaths are being taken.

In summary, no index of $\dot{V}A/\dot{Q}$ inequality is without potentially significant limitations, both quantitative and qualitative. However, if these limitations are recognized and the data interpreted accordingly, they remain very useful indices of clinical gas exchange function.

CHAPTER 15

Blood Gas Transport

Adrian Shifren
Robert A. Klocke

OXYGEN TRANSPORT

Oxygen is relatively insoluble in aqueous solutions such as blood. Dissolved oxygen alone is insufficient to meet the demands of tissue metabolism. Therefore, an alternate means of transporting oxygen is essential. Oxygen binds reversibly to hemoglobin, enabling the transport of large amounts of oxygen—approximately 20 mL/100 mL of blood at a hemoglobin concentration of 15 g/100 mL.

■ Oxygen Dissociation Curve

The oxygen dissociation curve represents the relationship between the oxygen content of blood and the partial pressure of oxygen to which it is exposed (Fig. 15-1).[1] Oxygen content is expressed as the volume of oxygen contained in 100 mL of blood but may also be expressed as either volumes % or mL/dL. The standard oxygen dissociation curve (Fig. 15-1) demonstrates the effects of oxygen–hemoglobin interaction at standard pH (7.40), temperature (37°C), and atmospheric pressure (760 mm Hg). The blue line at the bottom of the graph in Fig. 15-1 shows the amount of oxygen dissolved in blood, and the red line shows the total amount of oxygen in blood at any given oxygen tension. Almost the entire quantity of oxygen transported in blood is bound to hemoglobin. However, the role of dissolved oxygen cannot be ignored. Oxygen diffuses across the alveolar-capillary membrane, enters the plasma, traverses the red cell membrane, and enters the erythrocyte interior—all while dissolved in aqueous solutions. It then combines with hemoglobin enabling the transport of large amounts of oxygen to the metabolizing tissues. Dissolved oxygen, although present in very low concentration in blood, is a critical component of the process of O_2 exchange because hemoglobin cannot traverse endothelial and erythrocytic membranes.

Changes in the quaternary structure of hemoglobin that accompany oxygen binding result in a sigmoid, rather than hyperbolic, oxygen dissociation curve. The S-shaped dissociation curve is the result of changes in oxygen affinity of unbound heme groups following the binding of oxygen to another heme group in the same hemoglobin molecule. As illustrated in Fig. 15-1, once the partial pressure of oxygen reaches 90 to 100 mm Hg, hemoglobin is almost completely saturated with bound oxygen. There is little additional oxygen binding even at higher oxygen tensions. The relatively flat nature of the curve in this range of arterial oxygen tension is an advantage because reductions in arterial P_{O_2} (as might be caused by lung disease) will still allow for a relatively normal arterial O_2 content as long as arterial P_{O_2} remains ≥60 mm Hg. The normal partial pressure of oxygen in mixed venous blood at rest is ~40 mm Hg with an oxygen content of ~75% of maximum oxygen capacity. Thus, at rest only one-quarter of the oxygen delivered to body tissues is extracted from blood. However, oxygen extraction varies widely in different tissues. In addition, oxygen utilization changes appreciably during states of increased metabolism. In the tissues, the steep slope of the oxygen dissociation curve between 20 and 60 mm Hg facilitates the release of large amounts of oxygen with relatively moderate decrease in oxygen tension. This permits maintenance of blood oxygen tensions that promote diffusion of oxygen from the capillary blood into metabolizing tissues.

The maximum quantity of oxygen transported in blood is dependent upon hemoglobin concentration, which may vary moderately in normal circumstances but substantially in disease states. To facilitate comparison of oxygen dissociation curves with different hemoglobin concentrations, the ordinate of the curve can be normalized by expressing oxygen content as a percentage of the maximum possible oxygen content. This approach substitutes % saturation of hemoglobin for oxygen content, as illustrated in Fig. 15-2. Using this format, all normal oxygen dissociation curves are superimposable, regardless of differing hemoglobin concentrations.

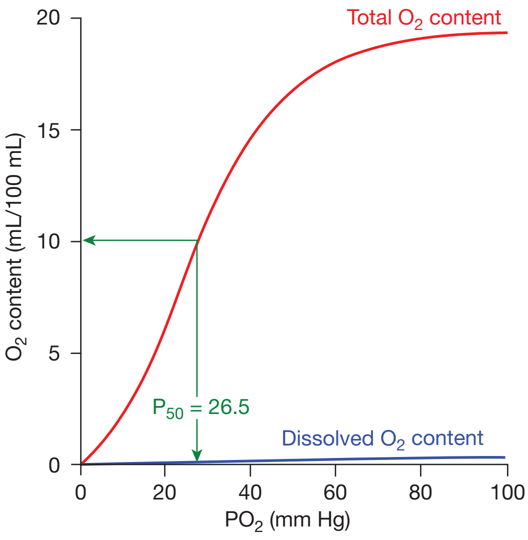

Figure 15-1 Oxygen dissociation curve. Relationship between oxygen content and pressure in normal human blood. The total oxygen content of blood as a function of the partial pressure of oxygen is indicated by the *red line*. The *blue line* indicates the content of dissolved oxygen resulting from changes in P_{O_2}. The partial pressure of oxygen (P_{50}) necessary to saturate one-half of hemoglobin in blood is indicated in *green*.

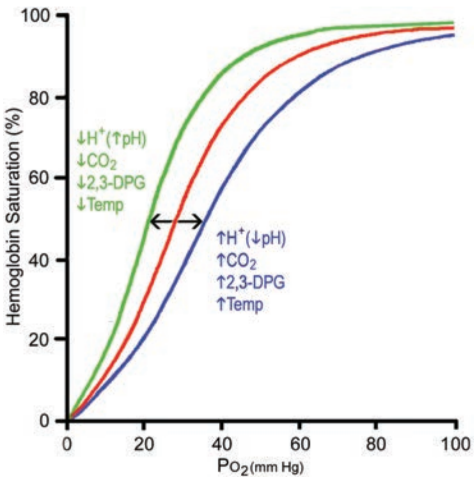

Figure 15-2 Oxygen dissociation curve. The ordinate is % saturation, the percentage of the maximum possible oxygen content. The normal oxygen dissociation curve is shown in *red*. The *green curve* is shifted to the left of the normal curve (increased oxygen affinity of hemoglobin) as a result of decreased blood hydrogen ion, decreased carbon dioxide, and 2,3-DPG concentrations or decreased temperature. The *blue curve* is shifted to the right (decreased oxygen affinity) of the normal curve caused by increases of these factors. The *black arrows* indicate the changes in P_{50}.

Alterations of Oxygen Affinity

The relationship between oxygen content and pressure can be affected by several factors. Increases in temperature, carbon dioxide tension, hydrogen ions (decreased pH), and 2,3-diphosphoglycerate (2,3-DPG) all shift the oxygen dissociation curve to the right.[1] This results in a decrease in the affinity of hemoglobin for oxygen, i.e., a greater oxygen tension is required to bind the same amount of oxygen to hemoglobin (Fig. 15-2). Conversely, decreases in temperature, carbon dioxide tension, hydrogen ions (increased pH), and 2,3-DPG shift the curve to the left, i.e., increase the affinity of hemoglobin for oxygen.[1] The degree of shift of the oxygen dissociation curve is described by the P_{50}, the partial pressure of oxygen required to achieve 50% oxygen saturation of hemoglobin. The normal P_{50} for human blood is 26.5 mm Hg (Fig. 15-1). The basic sigmoid nature of the relation between oxygen and hemoglobin does not change with alterations in the P_{50}. Rather, the curve is uniformly either stretched or compressed along the P_{O_2} axis.

The human erythrocyte contains large quantities of 2,3-DPG, an organic phosphate that is a product of glycolytic metabolism inside the erythrocytes. 2,3-DPG binds to the hemoglobin tetramer and decreases the O_2 affinity of hemoglobin.[1] The normal concentration of 2,3-DPG in erythrocytes is approximately 5 mM. However, this concentration can change significantly, thereby altering the P_{50}. There is a substantial change in the configuration of the hemoglobin tetramer between the oxygenated and deoxygenated states. The β-chains of the hemoglobin tetramer are more widely separated in the deoxygenated state than in the oxygenated state and have positive charges surrounding the central cavity of the hemoglobin tetramer. The widened gap between the β-chains of the deoxygenated molecule enables the highly negatively charged 2,3-DPG molecule to enter the space between the β-chains and bind electrostatically to four positively charged amino acids of the hemoglobin molecule. This tends to stabilize the hemoglobin molecule in the deoxygenated configuration. Higher pressures of oxygen are thus required to force the change in molecular configuration to the oxygenated form, resulting in a shift of the dissociation curve to the right along the P_{O_2} axis.

Most abnormal hemoglobins have normal oxygen equilibrium curves despite differences in amino acid sequences. Some relatively rare mutant hemoglobins are exceptions to this rule and exhibit increased O_2 affinity that is accompanied by erythrocytosis. Previously, measurements of P_{50} were advocated to investigate erythrocytosis, but identification of mutant hemoglobins with molecular techniques is far more likely to identify this rare cause of erythrocytosis.

Large quantities of carbon monoxide (CO) bound to hemoglobin can increase the affinity for oxygen of the remaining unbound sites on hemoglobin. The adverse effects of CO poisoning are twofold: (1) Binding of CO to hemoglobin interferes with oxygen binding and produces a functional anemia; and (2) binding of CO to hemoglobin also increases the affinity of hemoglobin for oxygen, thereby shifting the oxygen equilibrium curve to the left. This increased affinity hinders the release of oxygen in the tissues but is not as important as the functional anemia caused by CO binding.

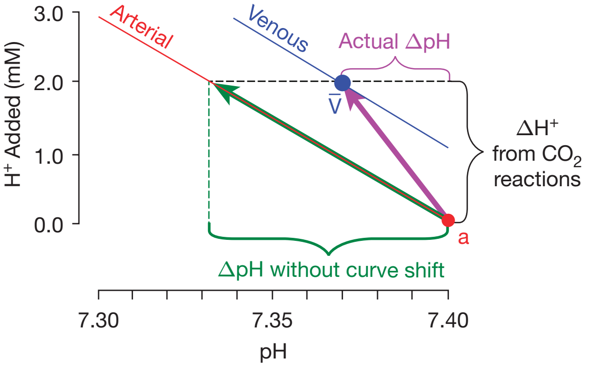

Figure 15-3 Buffer curves (change in pH produced by binding of hydrogen ions) of normal arterial (a) and mixed venous (v) blood. With release of oxygen bound to hemoglobin in tissues, buffering sites on the hemoglobin molecule increase their affinity for hydrogen ions, thereby shifting the buffer curve upward. The quantity of hydrogen ions (ΔH^+) added to blood by production of CO_2 in normal metabolizing tissues at rest is indicated by the *black bracket*. The figure shows the change in pH (*green bracket*) that would occur if buffering occurred only along the arterial buffer curve (*green arrow*). The actual, much smaller change in pH (*purple bracket*) that accompanies buffering (*purple arrow*) is due to the upward shift of the arterial buffering curve to the venous relationship that accompanies release of oxygen in the tissues. *(Reproduced with permission from Klocke RA: Encyclopedia of Respiratory Medicine. Philadelphia, PA: Elsevier; 2007.)*

Bohr Effect

The right shift of the oxygen dissociation curve produced by increases in P_{CO_2} and hydrogen ion concentration is known as the Bohr effect, named after the individual who first described the negative effect of increased P_{CO_2} on the oxygen affinity of hemoglobin. Both hydrogen ions and carbon dioxide bind at sites on the hemoglobin molecule that differ from the oxygen-binding sites.[2] However, there are many more sites that bind hydrogen ions than bind CO_2 molecules. Importantly, as the tertiary and quaternary configurations of the hemoglobin molecule change with release of oxygen, 16 of these hydrogen binding sites (14 histidine and 2 terminal amino groups) change their physiologic buffering capacities due to alterations in their acidic equilibrium constants (pKa).[3] The change in molecular configuration of hemoglobin causes some groups to increase their pKa and others to decrease their pKa. Two of the 16 Bohr buffering groups (one β-chain terminal amino group and one histidine [Lys82β] group) only contribute buffering activity during oxygen release when 2,3-DPG is bound to the hemoglobin molecule.[3] This is the usual situation inside the erythrocyte during normal circumstances. The net effect of the multiple changes in pKa increases the buffering power of hemoglobin at physiologic pH as bound oxygen is released from the hemoglobin tetramer. This is known as the alkaline Bohr effect. This effect minimizes the decrease in blood pH by buffering hydrogen ions released in CO_2 metabolism. Figure 15-3 illustrates the buffering curves of normal arterial and venous blood. Both exhibit effective, but parallel, buffering curves. As hemoglobin is deoxygenated, its buffering curve shifts upward (becomes greater), and significant amounts of hydrogen ion can be buffered with a smaller change in pH.[2] At rest, the decrease in blood pH accompanying tissue metabolism is reduced by one half due to buffering by the Bohr groups. Approximately half of the hydrogen ions released in aerobic metabolism are buffered in this manner (see "Haldane Effect," below).

It has been speculated that the increased carbon dioxide tension and hydrogen ion content in blood facilitate the release of oxygen bound to hemoglobin by shifting the oxygen dissociation curve to the right.[4] However, quantitative analysis indicates that this mechanism results in minimal augmentation of oxygen release in tissues at rest (2%–3%) because of the minute difference in pH between arterial and venous blood (0.03–0.05 pH units).[5] This effect becomes more significant during strenuous exercise with the production of lactic acid in anaerobic metabolism in heavily exercising muscle.[6] However, the main physiologic benefit of the Bohr effect is the increased buffering capacity of hemoglobin that accompanies release of oxygen from the hemoglobin molecule.[2,4]

Changes in Oxygen Affinity in Disease

Anemia or exposure to altitude impairs the ability to deliver oxygen to body tissues. The normal compensatory response to these situations is to increase 2,3-DPG concentration within the erythrocytes. This decreases the oxygen affinity of hemoglobin, thereby shifting the oxygen dissociation curve to the right. The loss of oxygen uptake at high oxygen tensions present in the lungs is small in this scenario because the right-shifted curve is very close to the normal curve at normal arterial oxygen tensions (Fig. 15-2). However, oxygen is released at a higher tension at the capillary level with a right-shifted curve. Since the P_{O_2} in the metabolizing mitochondria is close to zero, release of oxygen in the capillary at a higher P_{O_2} increases the oxygen tension gradient between the capillary and mitochondria. This augments diffusion of oxygen from the capillary to the site of its utilization. This is especially critical during elevated oxygen requirements or reduced organ perfusion.

Efforts have been made to produce shifts of the dissociation to the right in certain diseases or circumstances to improve oxygen delivery.[7] For example, the P_{50} of bank blood, even though stored at low temperature, can decrease dramatically after as little as 7 days of storage as a result of degradation of intraerythrocytic 2,3-DPG. Although stored blood is useful to expand intravascular volume, it may not be optimal in situations where oxygen delivery is impaired. This has prompted use of fresh blood in certain situations when large quantities of blood are needed, such as with open-heart surgery. To date there have been no definitive studies that have tested this hypothesis, largely due to the difficulty of determining the 2,3-DPG levels in transfused cells in a complex clinical setting. In normal, healthy humans with type A blood, it is possible to determine the level of 2,3-DPG in transfused type O cells essentially depleted of all 2,3-DPG by 35 days of storage.[8] Seven hours after transfusion, 2,3-DPG levels in type O transfused cells rise to approximately 50% of the level present before storage. In this study 2,3-DPG levels in the transfused cells reach 95% of the original levels prior to storage by 48 hours after trasfusion.[8]

In contrast to efforts to improve oxygen delivery to tissues by increasing P_{50}, recent work has suggested that decreasing P_{50} in patients with sickle cell disease may be clinically beneficial. When erythrocytes become sickled, the sickled cells may cause vaso-occlusive disease and are more likely to hemolyze, leading to substantial anemia. Voxelotor is a relatively small molecule (MW 337.4) that penetrates erythrocytes and binds reversibly to the N-terminal amino acid of the α-chain of hemoglobin.[9] The distribution of voxelotor between red cells and plasma is approximately 150:1, and the binding of voxelotor to hemoglobin decreases the P_{50}. This increases blood oxygen saturation in vivo, thereby decreasing red cell sickling in metabolizing tissues.

Vichinsky et al.[10] reported a randomized, double-blind study of 274 anemic patients with sickle cell disease (hemoglobin of 8–9 gm/dL) randomized in 1:1:1 ratio to treatment with either daily doses of 1500 mg or 900 mg of voxelotor or placebo. The primary endpoint was an increase of hemoglobin greater than 1.0 gm/dL after 24 weeks of therapy. Patient percentages reaching this goal were 51% in the 1500-mg group ($p = 0.001$) and 33% in the 900-mg group, compared with 7% in the control group. The change in the 900-mg group did not quite reach statistical significance. Laboratory measures of hemolysis provided evidence of decreased hemolysis in the patients treated with high-dose voxelotor. There was no evidence of reduced vaso-occlusive crises in any of the three groups. There were no adverse events reported with voxelotor in this study, although the possibility of tissue hypoxia secondary to reduction of the P_{50} was only monitored with usual clinical observations.

CARBON DIOXIDE TRANSPORT

Carbon dioxide (CO_2) is the primary by-product of aerobic metabolism. It is also generated through the buffering of hydrogen ions (H^+) released from organic acids, such as lactic acid and ketoacids. This buffering occurs through chemical reaction of H^+ ions with intracellular and extracellular bicarbonate ions (HCO_3^-). The CO_2 produced by these reactions diffuses into capillary blood and is carried in both chemical combination and physical solution to the lungs, where it is eliminated through expired ventilation. Similar to O_2 transport, most CO_2 in blood is not carried as dissolved gas, but rather as bicarbonate or bound to hemoglobin as carbamate.

Carbon Dioxide Dissociation Curve

Carbon dioxide is transported in three forms in blood: dissolved CO_2, bicarbonate ions, and carbamate compounds. The relationship between the blood content and partial pressure of CO_2 differs substantially from that of O_2. The total quantity of CO_2 contained in arterial blood is more than twice that of O_2 despite the lower partial pressures of CO_2. The CO_2 dissociation curve is very steep (Fig. 15-4). As a result, the difference in partial pressures of CO_2 between arterial and venous blood is small when compared to the large arterial–venous differences in blood P_{O_2}.[11] The total content of blood CO_2, that is, the vertical axis of the CO_2 dissociation curve, is the sum of all three forms of CO_2 (dissolved CO_2, bicarbonate, and carbamate).

Dissolved CO_2

Carbon dioxide is 20 times more soluble in aqueous solution than oxygen. However, this increased solubility is insufficient to facilitate transport of all the CO_2 produced by metabolism. Approximately

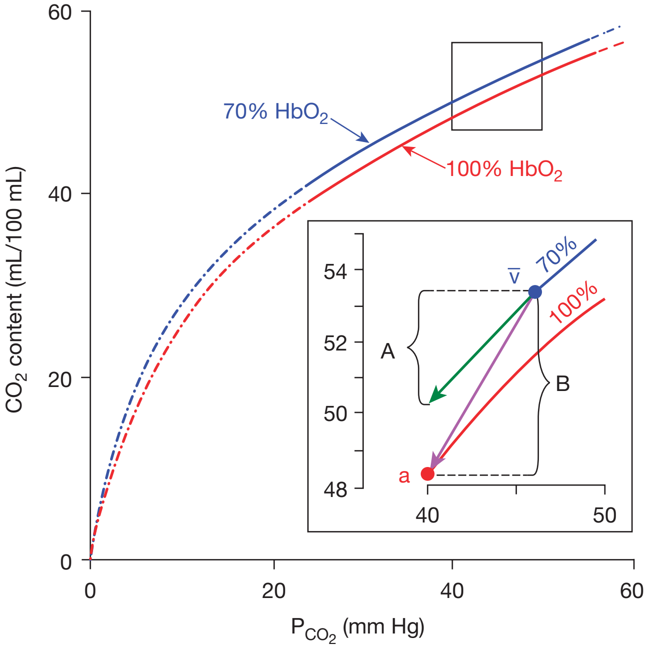

Figure 15-4 The Haldane effect showing the carbon dioxide dissociation curves of blood with 70% (*blue*) and 100% (*red*) oxygen saturations. The portions of the curves most commonly involved in gas exchange are drawn with *solid lines*. The P_{CO_2} and CO_2 contents of mixed venous ($\bar{v}$) and arterial blood (a) normally present at rest are shown in the enlarged inset. If there were no change in the CO_2 dissociation curve with oxygenation in the lung, the decrease in P_{CO_2} would take place along the venous curve (*green arrow*). This would produce a decrease in blood CO_2 content indicated by the vertical bracket A. The course of CO_2 exchange between arterial and mixed venous points is shown by the *purple arrow*. The enhanced CO_2 exchange produced by the Haldane effect is indicated by the greater vertical height of bracket B.

5% of total CO_2 content in blood exists as dissolved CO_2 in plasma and red cell water. Despite this, dissolved CO_2 has a critical role in gas exchange since only dissolved CO_2 crosses the alveolar–capillary membrane. Therefore, regardless of how CO_2 is transported in blood, each molecule must be converted into the dissolved form for excretion through ventilation. The quantity of dissolved CO_2 is directly proportional to the partial pressure of carbon dioxide in blood.

■ Bicarbonate

Carbon dioxide combines with water to form carbonic acid (H_2CO_3), which dissociates into a hydrogen and a bicarbonate ion.

$$CO_2 + H_2O \xleftrightarrow{\text{CA}} H_2CO_3 \leftrightarrow H^+ + HCO_3^- \qquad (1)$$

Because the pKa of carbonic acid is approximately 4.1, the actual concentration of carbonic acid in blood is minuscule. The overall pKa for reaction (1), including hydration of CO_2 and dissociation of carbonic acid to bicarbonate, is 6.1. The natural rate of formation of carbonic acid from CO_2 and water is very slow and takes seconds to minutes to reach completion in simple aqueous solutions. Under the influence of the carbonic anhydrase (CA) enzyme in the cytosol of erythrocytes, this reaction is increased by an overall factor of approximately 13,000.[11] CA inside red cells occurs as two isoenzymes. CA I is present in high concentrations in erythrocytes, but its activity is inhibited by intracellular chloride ions. CA II is present at one-sixth the concentration of CA I within red cells, but it is not inhibited by chloride ion and has a sevenfold greater intrinsic activity than CA I. Therefore, CA II is responsible for almost all the CO_2–bicarbonate catalysis in vivo.[11]

The presence of large, charged macromolecules on one side of a semipermeable membrane failing to distribute evenly across the membrane leads to an uneven distribution of charge across the membrane. This affects the distribution of small, permeable ions across the same membrane and is known as the Donnan effect. Hemoglobin and 2,3-DPG are both negatively charged and are confined to the red cell interior, leading to greater concentrations of permeable anions in plasma, principally chloride and bicarbonate, to maintain electroneutrality across the erythrocytic cell membrane. When bicarbonate is formed through the production and dissociation of carbonic acid (Equation 1), the intracellular concentration of bicarbonate rises leading to movement of bicarbonate from the red cell into the plasma. This disturbs the electroneutrality across the red cell membrane and is balanced by an equal movement of chloride into the red cell from the plasma in exchange for the exiting bicarbonate. Most anionic movement across the erythrocyte membrane is far too slow to achieve equilibrium during capillary transit time, but rapid exchange of the two anions is achieved via an exchanger located in the erythrocytic membrane.[12,13]

■ Carbamate

Carbon dioxide is also transported as carbamate compounds. Less than 10% of all exchanged CO_2 in blood binds to hemoglobin as carbamates, which are salts of carbamic acid formed by the reaction of CO_2 with amino groups on hemoglobin. CO_2 combines with uncharged terminal amino groups on the α and β chains of hemoglobin:

$$R - NH_3^+ \rightarrow H^+ + R - NH_2 \qquad (2)$$

$$R - NH_2 + CO_2 \rightarrow R - NHCOOH \rightarrow R - NHCOO^- + H^+ \qquad (3)$$

where R represents an N-terminal amino group of either the α or β chains of hemoglobin.[11] While any NH_2 group on hemoglobin can potentially bind CO_2 as a carbamate compound, only the N-terminal amino groups of hemoglobin participate in CO_2 exchange. At the pH present inside red cells, carbamic acid (R-NHCOOH) dissociates almost completely into a carbamate ion and a hydrogen ion. These H^+ ions, like those liberated by the formation of bicarbonate ions, are buffered substantially by hemoglobin (see "Haldane Effect," below).

Changes in the quaternary structure of hemoglobin accompanying binding and release of oxygen affect the pKs of reactions (2) and (3), altering the equilibrium between the NH_2 and NH_3^+ forms of the terminal amino groups. Because deoxygenated hemoglobin binds more CO_2 than oxygenated hemoglobin, more CO_2 can be carried as carbamate in venous blood at any given P_{CO_2} than in oxygenated arterial blood. The change in CO_2 binding between oxygenated and deoxygenated hemoglobin accounts for approximately one-eighth of the difference between the arterial and venous CO_2 contents during normal gas exchange. The physiologic importance of this process would be twice as great but is reduced by interactions between DPG and hemoglobin that limit carbamate formation.[11] Binding of the highly negatively charged DPG molecule to hemoglobin increases the number of N-terminal amino-NH_2 moieties to the positively charged amino-NH_3^+ forms that do not bind CO_2 as carbamate.

■ Haldane Effect

Oxygenated blood at any partial pressure of CO_2 contains less total CO_2 content than deoxygenated blood at the same partial pressure (Fig. 15-4). This is known as the *Haldane effect* after one of the investigators who first described the phenomenon.

Transport of CO_2 in blood as bicarbonate or carbamate is altered by blood oxygenation. These changes are described as "oxylabile" since they are dependent upon the state of hemoglobin oxygenation.[11] Changes in configuration of the hemoglobin molecule accompanying the release of oxygen facilitate binding of CO_2 to hemoglobin as carbamate, that is, *oxylabile carbamate formation*. This increases the total CO_2 content in deoxygenated blood compared with oxygenated blood.[14]

Formation of both bicarbonate ions and carbamate compounds releases large quantities of hydrogen ions. It is essential to buffer these hydrogen ions effectively to promote CO_2 transport. Deoxygenation of hemoglobin also results in a shift of the buffering curve of hemoglobin since deoxygenated hemoglobin is a stronger base than oxyhemoglobin. This shift permits binding of a greater number of hydrogen ions (Fig. 15-3). This *oxylabile buffering*, in turn, facilitates formation of larger quantities of carbamate and bicarbonate.[14]

The synergistic effects of oxygen and carbon dioxide transport result in a change in the carbon dioxide dissociation curve as oxygen is bound and released.[15] Approximately equal changes in bicarbonate and carbamate concentrations are responsible for the Haldane effect. Without the change between the oxygenated and partially deoxygenated CO_2 dissociation curves (the Haldane effect), the difference between arterial and venous CO_2 tensions would be approximately twice the normal value, thereby increasing tissue P_{CO_2}. Model calculations and in vitro data suggest that the Haldane effect accounts for 40% to 50% of total CO_2 exchange in the lung under normal conditions.[11,14,15]

CHAPTER 16

Diffusion, Chemical Reactions, and Diffusing Capacity

Robert A. Klocke
Adrian Shifren

INTRODUCTION

Uptake of oxygen and excretion of carbon dioxide require rapid, efficient exchange in the lung. The quantities of exchanged gases are staggering. For example, an 1800-calorie diet requires absorption of 375 L of oxygen per day, as well as excretion of a slightly smaller volume of carbon dioxide. Because blood remains in the pulmonary capillary bed for a limited time, the process of exchange must be accomplished in less than 0.75 s at rest and 0.5 s during exercise. This rapid, high-volume exchange occurs efficiently despite numerous interacting processes of diffusion and chemical reaction that occur in the lung. The rates of these processes are not only affected by intrinsic characteristics of blood but also determined by a host of other factors, including inspired oxygen fraction, alveolar gas tensions, cardiac output, and metabolic activity. The ease of exchange of respiratory gases belies the complexity of the overall process.

DIFFUSION

The concentration (C) of a gas dissolved in fluid depends upon its partial pressure (P) and solubility (α)

$$C = \alpha P \qquad (1)$$

Gases diffuse from a higher to a lower partial pressure, not necessarily from a higher to a lower concentration. This fact is especially pertinent when a gas diffuses between two phases, as occurs when O_2 and CO_2 are exchanged between alveolar gas and blood. For example, dissolved CO_2 diffuses down a partial pressure gradient from blood (46 mm Hg) into the alveolus (40 mm Hg), even though its actual concentration (millimoles of molecular CO_2 per liter of gas or blood) is greater in alveolar gas (2.5) than it is in venous blood (1.4).

Influence of Physical Properties

The rate of a gas diffusing through an aqueous membrane such as that separating alveolar gas and capillary blood is influenced by five factors. The rate is directly proportional to the surface area of the membrane, but inversely proportional to the thickness of the membrane. The rate increases in direct proportion to the difference in gas pressure between alveolar gas and capillary blood and with increases in diffusion and solubility coefficients of the gas in the membrane.

The diffusion coefficient of a gas in the alveolar–capillary membrane is largely a function of the size of the gas molecule, which is inversely proportional to the square root of its molecular weight (MW). Oxygen (MW 32) has a slightly greater diffusion coefficient than carbon dioxide (MW 44) in the alveolar membrane. However, the solubility of CO_2 in water, the major component of tissue composing the membrane, is much greater than the solubility of O_2. This difference far outweighs the effect of the slightly smaller size of the oxygen molecule. Thus, the rate of CO_2 transfer across the alveolar membrane is approximately 20 times greater than that of O_2 when both gases diffuse under the same partial pressure gradient. As a result, a much greater P_{O_2} gradient across the membrane is required to maintain O_2 transfer equal to that of CO_2.

On the other hand, the rate of carbon monoxide (CO) transfer is very similar to that of oxygen when both gases diffuse across the alveolar–capillary membrane under the same partial pressure gradient. CO (MW 28) is a slightly smaller molecule than oxygen, so its diffusion coefficient is slightly greater. This diffusive advantage is offset by a slightly lower aqueous solubility of CO compared to oxygen. As a result, CO and O_2 transfer across the membrane have approximately equal rates at the same transmembrane partial pressure gradient.

The rate of diffusion of a substance is affected by the viscosity of the medium through which diffusion occurs. Diffusion of a gas in air occurs at a rate that is four orders of magnitude greater than diffusion in water. Diffusion coefficients in tissues are only moderately less than those in water since most tissues are composed primarily of water. The interior of the erythrocyte is an exception to this general rule. As a consequence of the high concentration of hemoglobin inside the red cell, the viscosity of the cell contents is substantially greater than that of water. This greater viscosity reduces the diffusion coefficient for oxygen to one-third of its aqueous coefficient. The combination of increased viscosity and the large size of the hemoglobin molecule decreases the diffusion coefficient of hemoglobin within the red cell to less than 10% of its diffusion coefficient in a dilute aqueous solution. As a result, significant diffusion gradients are thought to exist within the red cell even though the distance between the cell membrane and the innermost portion of the cell is only a few microns.

Effect of Different Capacitances

The alveolar–capillary membrane provides a barrier to diffusion of gases between the alveoli and the capillaries. The rate of approach to diffusion equilibrium of a gas in the lung is dependent on the capacitances of the gas in the alveoli and blood relative to its solubility in the alveolar–capillary membrane. Normal ventilation of alveoli results in a large reservoir of oxygen with a pressure of ~100 mm Hg to promote diffusive transfer across the alveolar–capillary membrane. The ability of hemoglobin to bind O_2 increases the oxygen capacity of blood by two orders of magnitude compared with that of the alveolar–capillary membrane. This large capacitance for oxygen in blood requires substantial oxygen transfer across the membrane to reach diffusion equilibrium. Because the solubility of oxygen in the membrane is small relative to the large capacitances in alveolar gas and blood, oxygen exchange across the membrane requires 0.2 to 0.4 s to reach equilibrium.[1] Fortunately, this delay in reaching equilibrium is less than the average of 0.75 s that blood remains in the pulmonary capillary bed under resting conditions. These same conditions are present during carbon monoxide transfer. The large capacitance and the low aqueous solubility of CO lead to similar impediments in gas exchange.

In contrast to oxygen and carbon monoxide, the solubility of carbon dioxide in the membrane is sufficiently great compared to the capacitances of CO_2 in blood and alveoli to permit rapid equilibration of CO_2 across the alveolar–capillary membrane. CO_2 exchange requires a finite time for completion, but this delay is the result of the time needed to complete chemical and transport processes in blood and is not the result of slow diffusive transport across the alveolar–capillary membrane.

Gases transported in blood only in dissolved form are exchanged almost instantaneously across the alveolar–capillary membrane. As long as gas solubilities in the membrane and blood are similar, diffusion equilibrium between alveolar contents and blood is reached within 0.01 s because the normal alveolar–capillary membrane is extremely thin (median thickness of 0.3 μm). Only gases such as oxygen and carbon monoxide that have large alveolar and blood capacitances and reduced solubility in the alveolar–capillary membrane will require a finite time to reach diffusive equilibrium.

EXCHANGE OF OXYGEN AND CARBON MONOXIDE

Transport of respiratory gases entails numerous chemical reactions with the components of blood. Like diffusive transport of oxygen, these chemical reactions are not instantaneous and require finite periods of time to reach completion. It is commonly thought that diffusion provides the greatest time-dependent impediment to pulmonary gas exchange, but in actuality, chemical processes, especially those occurring in combination with diffusion or other chemical reactions, are more likely to slow rates of O_2 and CO_2 exchange.

From a stoichiometric viewpoint, the successive binding of O_2 to the heme moieties of hemoglobin is described by successive steps, each with separate association and dissociation rate constants. If the heme rings acted independently, these constants would be the same for each heme ring and the resulting dissociation curve would have a hyperbolic shape. However, binding of oxygen to one of the heme rings on the hemoglobin tetramer affects the affinity for O_2 of the remaining heme moieties of the molecule, leading to the familiar sigmoid shape of the oxygen dissociation curve.

Reactions of oxygen and hemoglobin during capillary transit are further complicated by the rate of oxygen diffusion through the viscous interior of the red cell. The chemical reactions of oxygen and hemoglobin occur quite rapidly in dilute hemoglobin solutions but proceed more slowly in red cell suspensions. Because of the large size of the hemoglobin molecule and increased viscosity of the red cell contents, hemoglobin molecules remain relatively immobile inside the red cell. As the red cell enters the pulmonary capillary, oxygen molecules bind to reduced hemoglobin molecules just inside the erythrocyte membrane. As these hemoglobin molecules become saturated, subsequent oxygen molecules entering the red cell must diffuse more deeply into the interior of the cell to reach reduced hemoglobin molecules. This combination of diffusion and chemical reaction causes oxygen uptake to occur as an "advancing front" that proceeds at a rate that is an order of magnitude slower than O_2 uptake in well-mixed, dilute hemoglobin solution. This combined process is complex and not easily described from a theoretical standpoint. As a result, the rate of oxygen uptake by hemoglobin contained in red cells is described by a single overall descriptive parameter, θ_{O_2}, which incorporates all the processes into a single phenomenologic value. The same approach is used to describe carbon monoxide uptake in blood. The rate at which CO replaces bound O_2 in blood is described by θ_{CO}.

The rates of O_2 and CO uptake by erythrocyte suspensions are determined in vitro and assumed to be representative of the rates of gas exchange in vivo. However, measurements of these rate constants in red cell suspensions in vitro may be affected adversely by methodologic artifacts. The actual rates of combination of O_2 and CO with red cells in vivo have not been measured and this leads to uncertainties in our complete understanding of exchange of these two gases in the lung.

SOURCES OF CO_2 EXCHANGED IN THE LUNGS

CO_2 is transported in blood as dissolved molecular CO_2, bicarbonate ion, and carbamate ion.[2] The relative contributions of each form of CO_2 content to the quantity of CO_2 excreted during gas exchange in the lung are not exactly proportional to their blood contents. Analysis of the differences between arterial and venous blood CO_2 contents can be used to calculate the amounts of each form of carbon dioxide content excreted in expired ventilation.[2] This analysis of differences between arterial and venous blood CO_2 contents is shown in Fig. 16-1.

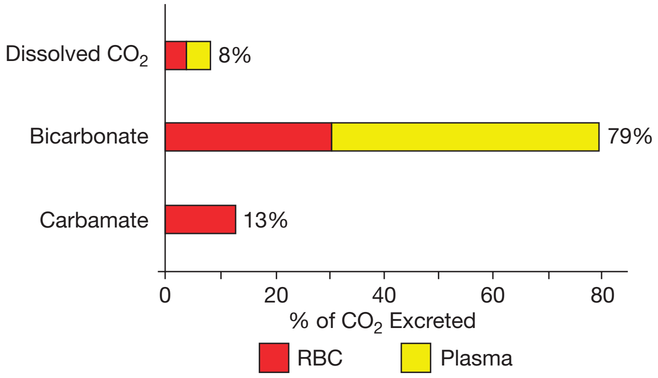

Figure 16-1 Sources of carbon dioxide excreted during passage of blood through the lungs in resting humans. The bars indicate the quantities of the different sources of CO_2 leaving blood from red cells *(red)* and plasma *(yellow)*. Bicarbonate contributes the overwhelming majority of CO_2 to the expired ventilation. As indicated in the figure, the majority of excreted bicarbonate enters the lung in plasma and is exchanged for chloride to reach carbonic anhydrase and hemoglobin buffering capacity within the red cell. *(Data from Farhi LE, Tenney SM: Handbook of Physiology. Section 3, The Respiratory System, vol 4. Bethesda, MD: American Physiological Society; 1987.)*

Dissolved CO_2 Exchange

Because CO_2 is more soluble than O_2 in the alveolar–capillary membrane, it often is assumed that overall CO_2 exchange occurs much more rapidly than O_2 exchange. As blood enters the pulmonary capillary bed, dissolved CO_2 immediately diffuses into the alveoli and capillary blood P_{CO_2} falls to the level present in the alveolar gas. However, this is a minimal amount of the total carbon dioxide that must be excreted in expired ventilation. The vast remainder of CO_2 is transported as bicarbonate and carbamate and the conversion of these forms to dissolved CO_2 limits the rate of CO_2 exchange.[2,3] As a result, CO_2 exchange proceeds more slowly than oxygen exchange. This is illustrated in Fig. 16-2, *Upper Panel*, when a bolus of dissolved CO_2 and an inert gas such as acetylene is injected into an isolated lung perfused with saline buffer. CO_2 is rapidly exchanged, similar to the inert gas acetylene. In contrast, when a bicarbonate bolus and dissolved acetylene is injected into the same preparation (Fig. 16-2, *Lower Panel*), CO_2 exchange lags behind acetylene excretion for a finite period of time until bicarbonate is converted into dissolved CO_2 that can cross the alveolar–capillary membrane.[4]

Bicarbonate Exchange

Bicarbonate ion combines with hydrogen ion extremely rapidly to form carbonic acid (H_2CO_3). The natural rate of dehydration of carbonic acid to CO_2 and water is a slow process, requiring 60 to 90 s to reach completion. However, this reaction is catalyzed inside the red cells by a factor of ~13,000 by the large concentration of carbonic anhydrase (CA) contained in red cells.[2]

$$HCO_3^- + H^+ \rightarrow H_2CO_3 \xrightarrow{CA} CO_2 + H_2O \qquad (2)$$

The substantial buffering capacity of hemoglobin inside the erythrocyte, augmented by the simultaneous conversion of reduced to oxygenated hemoglobin (Bohr Effect), provides the hydrogen ions required for this reaction. The dissolved CO_2 formed by this reaction inside the red cell leaves the blood and enters the alveoli, but continuing excretion of CO_2 is still dependent upon continuing conversion of bicarbonate to CO_2. Inside the red cell, the catalyzed formation of dissolved CO_2 rapidly (~0.1 s) depletes the concentration of intracellular bicarbonate and the production of CO_2 slows substantially.[1,5]

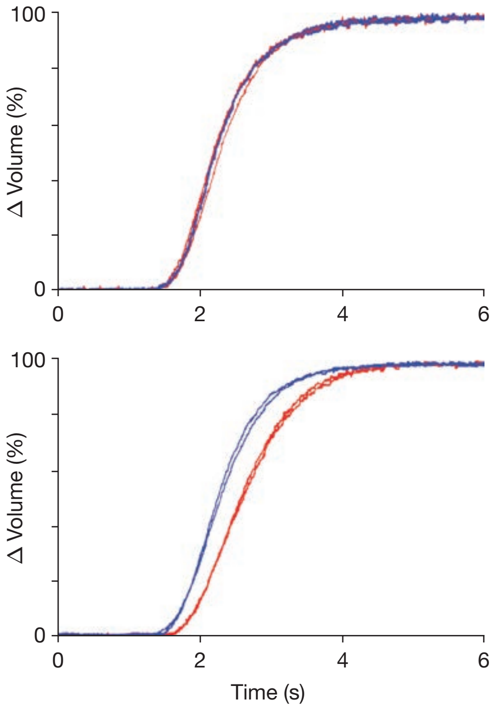

Figure 16-2 Rates of acetylene *(blue curves)* and CO_2 *(red curves)* excretion after two pairs of injections into the pulmonary artery of a single isolated lung preparation perfused with buffer. Volume changes are normalized to facilitate comparison. *Upper Panel*: The excretion of both acetylene and CO_2 proceeds at the same rate after injections of buffer containing either dissolved CO_2 or acetylene. Differences in mean transit times for CO_2 and acetylene were essentially the same (−0.027 s for first pair and +0.022 s for second pair of injections). Thus, dissolved CO_2 crosses the alveolar–capillary membrane at the same rapid rate as the inert gas acetylene. *Lower Panel*: The excretion of CO_2 generated from injections of bicarbonate *(red curves)* lags substantially behind the excretion of dissolved acetylene (*blue curves*) (+0.301 s in the first set of paired injections and +0.312 s in the second set of paired injections). This slower excretion of CO_2 is caused by the time required to convert bicarbonate to CO_2 with catalysis in this experiment provided by carbonic anhydrase localized to the capillary endothelium. *(Reproduced with permission from Schünemann HJ, Klocke RA. Influence of carbon dioxide kinetics on pulmonary carbon dioxide exchange. J Appl Physiol (1985). 1993;74(2):715–721.)*

Bicarbonate accounts for the majority (~79%) of the CO_2 excreted in the lungs under resting conditions (Fig. 16-1). Of this 79%, 30% entered the lung inside the erythrocytes and 49% in the plasma. There is a minimal amount of CA attached to the interior surface of the pulmonary capillaries, but its activity is ~1% of the erythrocytic enzyme. As a result, little or no conversion of bicarbonate to dissolved CO_2 occurs in the plasma during the short pulmonary capillary transit time (0.75 s at rest, 0.5 s during exercise). The quantity of bicarbonate transported in plasma is much greater than that carried within the red cells for three reasons. First, plasma volume constitutes 55% and erythrocytes only 45% of the total blood volume. Second, bicarbonate is present only in the volume of water in each component; plasma water content (95%) is substantially greater than erythrocyte water content (72%). Third, because of the Donnan distribution of anions across the erythrocyte membrane (see Chapter 15), bicarbonate concentration inside the red cell is only 63% of the plasma concentration.

As the intracellular concentration of bicarbonate decreases, plasma bicarbonate enters the cell in exchange for intracellular chloride. Bicarbonate–chloride movement across the erythrocyte membrane occurs in an electrically neutral, one-for-one exchange that is facilitated by an anion exchange protein present in the erythrocyte membrane.[2] Despite the presence of approximately one million anion exchangers with an extremely rapid turnover (50,000 ions per second) in each red cell membrane, bicarbonate–chloride exchange requires 0.3 to 0.4 s to reach completion.[6] This ionic exchange permits the continuing production of dissolved CO_2 from bicarbonate that entered the lung capillary bed in the plasma compartment of blood.

The delay between acetylene and CO_2 excretion shown in the lower panel of Fig. 16-2 illustrates the lag in CO_2 excretion that occurs if any chemical reaction or transport process is required to convert bicarbonate or carbamate into dissolved CO_2 to be excreted in the lungs. In the experimental data shown in the figure, bicarbonate conversion to CO_2 is catalyzed by a small amount of carbonic anhydrase located on the capillary endothelium. If red cells were present, the conversion to dissolved CO_2 inside the red cell would occur much more rapidly (~0.1 s) because of the large quantity of carbonic anhydrase inside red cells. However, as described above, the majority of bicarbonate entering the pulmonary capillary bed in plasma first has to enter the red cell to access intraerythrocytic carbonic anhydrase, a relatively slow process compared to exchange of dissolved CO_2 in the lung. Thus, although dissolved carbon dioxide entering the pulmonary capillaries is exchanged extremely rapidly, the CO_2 exchange derived from bicarbonate conversion is delayed by chemical and transport processes.

■ Carbamate Exchange

Besides exchange of dissolved CO_2 and bicarbonate, a modest amount of CO_2 excretion results from release of CO_2 bound to hemoglobin as carbamate.[2] The latter is a salt of a carbamic acid formed by reaction of CO_2 with terminal amino groups of the four chains of the hemoglobin molecule. The release of CO_2 bound as carbamate is caused by the alteration of the molecular conformation of hemoglobin that accompanies oxygenation. This change in configuration favors formation of the charged amino group that does not bind CO_2 (see Equations 2 and 3, Chapter 15). The carbamate reaction is complete in 0.2 to 0.3 s but cannot occur until hemoglobin is first oxygenated. The process of oxygenation further delays conversion of carbamate to dissolved CO_2. As a result, conversion of carbamate is a relatively time-consuming process that slows its actual excretion as dissolved CO_2.

In summary, exchange of CO_2 in the lung is thought to require at least ~0.4 to 0.5 or more seconds because of the series of processes that are necessary to convert CO_2 transported as bicarbonate and carbamate to dissolved CO_2.[1,5] In fact, computational models of CO_2 exchange suggest that in some circumstances total chemical and transport processes do not quite reach equilibrium prior to blood leaving the pulmonary capillary.[1,5] Even in the worst case, the degree of disequilibrium is small and a minimal increase in ventilation can easily compensate for a slight impairment of the rate of CO_2 exchange.

GASES USED TO MEASURE DIFFUSING CAPACITY

The pulmonary diffusing capacity (DL) of a gas provides an estimate of its rate of transfer from the alveoli into capillary blood. Initially investigators thought that only diffusion of gas across the alveolar-capillary membrane limited exchange. This is the case for inert gases and, as noted earlier, equilibrium of these gases is achieved rapidly even in disease. However, transfer of gases that combine with hemoglobin are limited both by diffusion across the alveolar membrane and by the rate of reactions inside red blood cells. The only gases that have measurable diffusing capacities are those with low solubility in the pulmonary membrane and high capacitance in blood as a result of binding to hemoglobin. These gases include oxygen (O_2), carbon monoxide (CO), and nitric oxide (NO).

OXYGEN DIFFUSING CAPACITY (DL_{O_2})

The diffusing capacity is calculated as the volume of gas absorbed by pulmonary blood per unit time ($\dot{V}$) divided by the pressure gradient between alveolar gas (PA) and pulmonary capillary blood (Pcap).

For oxygen,

$$DL_{O_2} = \frac{\dot{V}_{O_2}}{PA_{O_2} - Pcap_{O_2}} \tag{3}$$

Measurement of DL_{O_2} is difficult because, in addition to diffusion, O_2 transfer may be limited by other mechanisms, such as ventilation–perfusion mismatching and shunting. The measurement is further complicated by a changing capillary P_{O_2} during capillary transit that cannot be accurately determined. These difficulties have led investigators to abandon attempts to measure the diffusing capacity of oxygen.

CARBON MONOXIDE DIFFUSING CAPACITY (DL_{CO})

Carbon monoxide provides an excellent alternative to measuring diffusing capacity because CO normally is present in minimal amounts in blood and binds to hemoglobin, similar to O_2. Because capillary P_{CO} is extremely low in usual circumstances, it can be assumed to be negligible and DL_{CO} is calculated by dividing CO uptake ($\dot{V}_{CO}$) by alveolar P_{CO}.

Measurement of the Single-Breath Diffusing Capacity

Several different techniques can be used to measure the carbon monoxide diffusing capacity. The steady-state and rebreathing methods of determining DL_{CO} are employed in relatively few clinical laboratories. The steady-state method usually is performed in subjects who are exercising on a treadmill or stationary bicycle, thereby limiting its clinical application in some patients. The rebreathing methodology requires rapid-responding gas analyzers and has technical requirements that are not available in most clinical laboratories. The single-breath technique is the method utilized in clinical pulmonary function laboratories because of its relative technical ease and the ability of patients to perform the respiratory maneuvers. The patient performs a maximum expiration to residual volume followed by a maximum inspiration to the total lung capacity of a gas mixture of 0.3% carbon monoxide, 21% oxygen, an inert tracer gas with low aqueous solubility (usually helium or methane), and balance nitrogen. After the inspiration of this gas mixture, the breath is held for 10 s followed by a maximum expiration. After the expired volume is sufficient to clear the volume of the tracheobronchial dead space in which gas exchange does not occur, a gas sample is obtained. Analysis of the CO and tracer gas concentrations in the expired gas permits calculation of the diffusing capacity.

The volume of CO absorbed in the lungs can be calculated from the alveolar volume and the initial and final concentrations of CO in alveolar gas. The rate of CO uptake during the breath-hold is a function of the alveolar PA_{CO}, which falls exponentially during the breath-hold. Capillary CO pressure is assumed to be equal to zero. The single-breath diffusing capacity is calculated by:

$$DL_{CO} = \frac{60 VA}{t_{bh}\,(PB - 47)} \ln \frac{FA_{CO\ \text{initial}}}{FA_{CO\ \text{final}}} \tag{4}$$

where

60 = the number of seconds per minute
VA = the alveolar volume of gas (mL_{STPD}) present in the lung during the breath-hold
t_{bh} = the duration of the breath-hold (seconds)
$PB - 47$ = the barometric pressure (mm Hg) – water vapor pressure at 37°C
FA_{CO} = the alveolar fraction of carbon monoxide at the initial and final times of the breath-holding period

The minimally soluble inert gas included in the inspired volume is not significantly absorbed in capillary blood and is diluted in the lung volume present at the start of the maximal inspiration. Alveolar volume (VA) is calculated from the dilution of the tracer (helium in this example) and the inspired volume (VI):

$$VA = VI\frac{FI_{He}}{FA_{He}} \tag{5}$$

where

FI_{He} and FA_{He} = the inspired and alveolar helium concentrations

The alveolar fraction of helium and the final alveolar CO fraction are obtained by measuring CO and He concentrations in the expired alveolar gas sample. The initial alveolar CO fraction (FA_{CO}) is calculated from the dilution of the inspired CO in the volume of gas present in the lung during the breath-hold,

$$FA_{co} = FI_{co}\frac{VI}{VA} \tag{6}$$

where

FI_{CO} = the inspired CO fraction

Calculation of the diffusing capacity is based on the assumption that the lung is homogeneous, that is, all portions of the lung have the same relative ventilation, perfusion, alveolar volume, and diffusing capacity.

The single-breath method requires patient cooperation to perform the necessary respiratory maneuvers. A patient with an extremely reduced lung volume may not have a vital capacity large enough to sufficiently clear the dead space and provide a sufficient sample for analysis of alveolar gas concentrations. The ability to hold the breath for 10 s also limits applicability to some patients. Finally, this method can be employed only in the resting state since few patients can hold their breath during exercise. Despite these limitations, the single-breath DL_{CO} is the most practical and widely used method for measuring DL_{CO}. The technical aspects of the test have been standardized so that the same methodology is utilized in different laboratories.[7]

Measurement of Dm and V_c

Similar to oxygen, CO uptake is limited both by diffusion across the alveolar–capillary membrane and by chemical reaction of CO with intracellular hemoglobin. As described by Roughton and Forster,[8] DL_{CO} can be viewed as a composite of two elements:

$$\frac{1}{DL_{CO}} = \frac{1}{Dm_{CO}} + \frac{1}{\theta_{CO} V_C} \tag{7}$$

where

Dm_{CO} = the diffusing capacity of the alveolar–capillary membrane for CO
θ_{CO} = the rate of displacement of O_2 from red cell hemoglobin by CO
V_C = the volume of blood in the pulmonary capillary bed

Because O_2 and CO compete for binding sites on hemoglobin, CO binding is inhibited by increases in P_{O_2}. Thus, DL_{CO} and θ_{CO} vary inversely with P_{O_2}. Using in vitro values of θ_{CO} and two measurements of DL_{CO} at normal and elevated inspired O_2 concentrations, Equation (7) can be solved to provide values of both Dm_{CO} and V_C. In most clinical circumstances, only DL_{CO} breathing gas with a normal oxygen concentration is measured because of the requirement to perform two diffusing capacities with different fractions of inspired oxygen in patients needed to measure Dm and V_C.

Unfortunately, there is uncertainty regarding the actual values of θ for any gas that binds to hemoglobin contained in erythrocytes in humans in vivo. In vitro measurements of θ have utilized rapid reaction techniques that may be flawed due to unstirred layers of fluid surrounding red cells in a dilute suspension used in the experimental apparatus. This artifact is greater the more rapidly that the gas reacts with hemoglobin ($NO > O_2 > CO$). Furthermore, the rate of gas uptake by erythrocytes may be influenced by the ability of the red cells to be deformed during passage through the pulmonary capillaries, a factor not present during in vitro measurements of θ. Mathematical models suggest that the rate of uptake of gases also depends on erythrocyte orientation and spacing within capillaries. Since the characteristics of erythrocyte transit in the capillary bed have not been defined, extrapolation of in vitro measurements to the in vivo situation introduces uncertainties in the data. Despite these reservations, solution of Equation (7) using values of θ_{CO} determined in vitro yields values of Dm_{CO} and V_C that agree fairly well with independent estimates of these variables using alternative experimental techniques such as morphometry. These calculations indicate pulmonary capillary blood volume (V_C) at rest of 75 to 100 mL for men and slightly less for women.

NITRIC OXIDE DIFFUSING CAPACITY ($D_{L_{NO}}$)

Nitric oxide binds to hemoglobin at the same sites as O_2 and CO, but the rate of NO binding is much more rapid. Since NO binds to hemoglobin in solution two orders of magnitude faster than the rate of CO binding, it has been postulated that θ_{NO} is much greater than θ_{CO} and approaches a value of infinity. If this is the case, then the term $1/\theta_{NO}V_C$ (analogous to Equation (7) for CO) approaches zero and the diffusing capacity measured with NO should reflect only the resistance to gas transfer provided by the alveolar–capillary membrane, that is, the Dm_{CO} component of the CO diffusing capacity.

Unfortunately, there is uncertainty regarding the actual values of θ_{NO} that binds to hemoglobin contained in erythrocytes in humans in vivo.[9] In vitro measurements of θ_{NO} have utilized rapid reaction techniques that may be flawed due to unstirred layers of fluid surrounding red cells in a dilute suspension used in the experimental apparatus. This artifact is greater the more rapidly that the gas reacts with hemoglobin.

Furthermore, the rate of gas uptake by erythrocytes may be influenced by the ability of the red cells to be deformed during passage through the pulmonary capillaries, a factor not present during in vitro measurements of θ_{NO}. In addition, calculations of Dm and V_C using simultaneous CO and NO diffusing capacity measurements often provide substantially different values. As a result of these issues, it is premature to speculate on the potential clinical value of measurements of $D_{L_{NO}}$ until these underlying problems are clarified. In addition, measurement of $D_{L_{NO}}$ requires sophisticated equipment and technical expertise that only are present in research settings.

FACTORS INFLUENCING THE DIFFUSING CAPACITY

The CO diffusing capacity originally was thought to reflect the resistance of the alveolar–capillary membrane to transfer of CO from the alveoli to capillary blood. The classic work of Roughton and Forster[8] elucidated the influence of chemical reactions on transfer of CO. $D_{L_{CO}}$ may be a measure of decreased gas transfer caused by abnormal diffusion, but also can reflect reduction in hemoglobin concentration, nonuniform distribution of physiologic properties throughout the lung, or loss of lung tissue. Because multiple factors in addition to diffusion can affect $D_{L_{CO}}$, in Europe this test is often termed the CO transfer factor, rather than the CO diffusing capacity. If correction for factors that affect measured $D_{L_{CO}}$ are performed, the predicted values, not the measured values, of $D_{L_{CO}}$ should be adjusted.[7]

Hemoglobin Concentration

Capillary blood volume (V_C) is a prime variable in the diffusing capacity. Its importance is due to the quantity of hemoglobin available to combine with CO within the capillary bed. The calculated value of V_C can be reduced directly by diseases that decrease capillary volume, but also can vary with the concentration of hemoglobin in blood. For this reason, the predicted $D_{L_{CO}}$ can be corrected for alterations in hemoglobin concentration.[7] For adult males and adolescents:

$$\begin{aligned}&\text{Predicted } D_{L_{CO}} \text{ (Corrected)}\\ &= \text{Predicted } D_{L_{CO}}\ (1.7\ \text{Hb}/(10.22 + \text{Hb}))\end{aligned} \tag{8}$$

where

Hb = hemoglobin concentration expressed in g/dL

For adult women and children less than age 15, the factor of 10.22 in Equation (8) is replaced by a factor of 9.38. Unfortunately, most clinical laboratories do not correct the predicted value of $D_{L_{CO}}$ for abnormal hemoglobin values.

Partial Pressure of Alveolar Oxygen

As indicated previously, the actual value of θ_{CO} depends on P_{O_2}. Increased alveolar P_{O_2} will reduce measured $D_{L_{CO}}$. Therefore, measured $D_{L_{CO}}$ will be lowered if patients receive supplemental oxygen prior to the actual measurement. Conversely, reduced alveolar P_{O_2} will lead to an increment in measured $D_{L_{CO}}$. This has led to the suggestion to correct predicted $D_{L_{CO}}$ if the measurement was made with an altered inspired oxygen fraction or at altitude.

Body Position

$D_{L_{CO}}$ is 5% to 15% greater in the supine position than in the erect position. Blood volume shifts from the lower trunk and legs to the lungs when in the supine position. Most of the increase in $D_{L_{CO}}$ appears to be due to a 13% to 27% increase in V_C accompanying the fluid shift. However, there is also a minimal increase in Dm_{CO} in the supine position, possibly the result of recruitment of capillaries by the increased intravascular volume. The effect of posture on $D_{L_{CO}}$ decreases with age, but the reasons underlying this observation remain unknown.

Exercise

$D_{L_{CO}}$ can increase as much as twofold during exercise. This increase is attributed to proportionally equal increases in both Dm and V_C. Both alveolar–capillary surface area and capillary volume are recruited by the increase in cardiac output that accompanies exercise. The transit time through the capillary bed decreases, but not to the same degree as would be predicted in a vascular bed with fixed resistance. The potential reduction in transit time is partially offset by recruitment and distention of the pulmonary capillary bed.

Theoretically, $D_{L_{CO}}$ must have a maximum that cannot be exceeded when the entire pulmonary capillary bed and alveolar surface have been recruited. This should lead to a plateau in measured $D_{L_{CO}}$ even though the level of exercise continues to increase. This has not been observed in humans. Using a unique animal model of conscious greyhounds exercising on a treadmill, Carlin et al.[10] could not demonstrate a plateau in $D_{L_{CO}}$ with increasing exercise even though oxygen uptake reached a level of approximately 120 mL/kg/min. This level of O_2 uptake is almost twice that seen in highly trained humans. Thus, it seems unlikely that the diffusing capacity in humans reaches a plateau during maximal exercise, but this does not rule out the possibility that oxygen exchange is limited by diffusion in this circumstance. Disequilibrium may occur before maximum recruitment of the diffusing capacity because capillary transit time may be less than the time required for O_2 exchange to be completed. Evidence in humans suggests that blood may leave the capillary bed without attaining complete equilibrium between alveolar P_{O_2} and capillary

P_{O_2} at sea level in some highly trained athletes during maximal exercise. This also can occur in normal individuals at extreme altitude, which results in a marked reduction in the inspired P_{O_2}.

■ Alveolar Volume

DL_{CO} decreases with reduction in alveolar volume due to accompanying decreases in DL_{CO} and V_C. This occurs with an inadequate inspiration to total lung capacity in persons with normal lungs, or with maximal inspiration in patients whose total lung capacities have been reduced by disease. In an effort to correct for alterations in alveolar volume rather than a true loss of diffusing capacity, some clinicians and investigators normalize DL_{CO} by dividing the observed DL_{CO} by the alveolar volume present during the measurement. This ratio of DL_{CO}/VA will be a useful index only if two assumptions are valid. First, there must be an approximately linear relation between DL_{CO} and VA. This assumption is reasonable at lung volumes greater than 50% of total lung capacity, but not at lower lung volumes. Second, the relation between DL_{CO} and VA must be directly proportional (i.e., a graph of DL_{CO} vs. VA must pass through the origin of the graph). This clearly is not the case. DL_{CO}/VA is not constant in normal persons and varies as alveolar volume changes.[11] Although frequently used, the DL_{CO}/VA ratio alone does not provide a valid index of the effect of changes in alveolar volume.[7,11,12]

■ Nonuniform Distribution of Physiological Properties

Calculation of DL_{CO}, regardless of the method used to make the measurement, implicitly assumes that the lung is completely uniform with regard to ventilation, alveolar volume, perfusion, and diffusive properties. This requires that each gas exchange unit possesses the same relationship among all these physiologic properties, an assumption that is not completely valid even in normal, healthy persons. The most important factor determining CO uptake is the relationship of local diffusing capacity to local blood flow, the ratio of DL_{CO}/Q. Nonuniform distribution of important physiologic variables throughout the lung produces a decrease in diffusing capacity and, by analogy, a reduced ability to transfer oxygen from the inspired air to capillary blood. Transfer is further complicated by the nonlinear nature of the processes involved. For example, the oxygen dissociation curve of hemoglobin has a sigmoid shape, and a change in alveolar P_{O_2} may have a large or a minimal effect on the quantity of O_2 exchanged depending on the absolute value of the P_{O_2}. Disruptions of these complex relationships among physiologic parameters have variable effects on O_2 transfer. The contributions of individual pathophysiologic deviations cannot be assessed by a global measurement such as the diffusing capacity. Thus, DL_{CO} provides a means of assessing overall oxygen exchange but does not indicate specific defects in gas exchange.

TECHNICAL CONSIDERATIONS

Measurements of DL_{CO} have greater variation than spirometric observations such as the forced vital capacity (FVC) or forced expiratory volume in 1 s (FEV_1). Criteria for acceptable measurements of DL_{CO} have been based upon relative or absolute differences between repeated measurements. The European Respiratory Society/American Thoracic Society (ERS/ATS) consensus statement[7] recommends reporting the average of two measurements, both of which agree within 2.0 mL/min/mm Hg or within 10% of the higher measured value. Punjabi et al.[13] reported that an absolute difference of 2.5 mL/min/mm Hg between duplicate measurements could be achieved in 96% of patients. This criterion was deemed more reasonable than a percentage variation because it remained constant over a wide range of measured values in contrast to a changing percentage criterion. The strength of this study is in its size (more than 6000 patients) and its performance during routine pulmonary testing in a single clinical setting. A drawback to its universal application is that three or more determinations of DL_{CO} were required in one-half of patients to meet criteria of acceptability. It is important to note that some clinical laboratories will perform only a single diffusing capacity measurement and report this value rather than reporting the mean of at least two acceptable determinations. This obviously increases the variability of reported values and lessens the ability to compare measurements over a period of time.

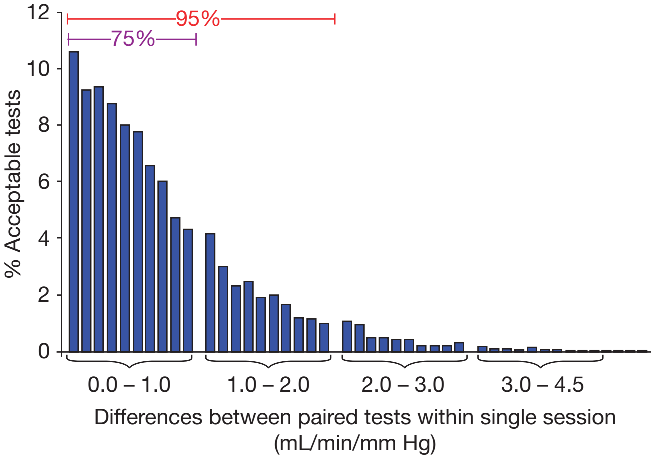

Figure 16-3 Differences between pairs of DL_{CO} measured within a single session in 4732 patients who had acceptable DL_{CO} efforts. The bars in the figure include differences in 75% of paired measurements *(purple)* and the differences in 95% of paired measurements *(red). (Data from Wise RA, Teeter JG, Jensen RL, et al. Standardization of the single-breath diffusing capacity in a multicenter clinical trial. Chest. 2007;132(4):1191–1197.)*

There is considerable variation in measurements of DL_{CO} among different clinical laboratories. These differences can be overcome by following strict technical protocols. In a carefully controlled multicenter (33 sites) clinical trial, Wise et al.[14] reported that 75% and 95% of the differences between duplicate DL_{CO} determinations with acceptable subject efforts (4797 pairs) were within <1 and <2 mL/min/mm Hg, respectively (Fig. 16-3). Acceptable criteria included inspired volume >90% of the FVC and a breath-hold time of 9–11 s.

The time of the breath-holding maneuver in the single-breath method requires patient cooperation. Because of nonuniform distribution of physiologic variables, CO uptake does not occur in a strictly exponential fashion even in some healthy persons. As a result, measured DL_{CO} decreases slightly with prolonged breath-hold in normal subjects. This decrement can be substantially greater in patients with lung disease. The empirical breath-holding time of 10 s was chosen as a practical compromise to permit measurable CO uptake but still be feasible for patients to perform. Many laboratories set a breath-hold range of 9 to 11 s as acceptable, although the ERS/ATS consensus report[7] stipulates a range of 8 to 12 s. Patients with lung disease often cannot perform rapid respiratory maneuvers mandated by the single breath DL_{CO} measurement. Slower flow rates prolong the time required for inspiration and expiration. As a result, instantaneous, uniform mixing of alveolar contents assumed in the calculation of DL_{CO} is not achieved. This may lead to a decrement in the reported measurement.

Most laboratories request that patients refrain from smoking for variable periods of time prior to measurement of DL_{CO} to avoid accumulation of CO in blood. Significant elevation of carboxyhemoglobin reduces measured DL_{CO} in two ways. First, the presence of carboxyhemoglobin produces a functional anemia, lessening the capacity of hemoglobin to bind O_2 or CO. This reduces the $\theta_{CO}V_C$ component of DL_{CO}. Second, calculation of DL_{CO} assumes that the back pressure of

CO in the capillary is zero, and the gradient for CO transfer is equal to PA_{CO}. The presence of carboxyhemoglobin in blood produces an actual alveolar-capillary P_{CO} gradient less than that assumed in the calculation, thereby leading to a lower calculated value of DL_{CO}. Graham et al.[15] measured the effect of experimental elevation of carboxyhemoglobin in normal individuals. Values of DL_{CO} obtained with the usual single-breath calculation decreased approximately 1.5% from the true value for each 1.0% elevation of blood carboxyhemoglobin. Although algorithms are available to correct observed DL_{CO} for carboxyhemoglobin effects, it is preferable to make the measurement without a significant elevation of carboxyhemoglobin. At a minimum, 12 hours of abstinence from smoking is advisable in patients who smoke extensively because carboxyhemoglobin levels as great as 6% to 12% are observed immediately following tobacco usage.

Measurement of DL_{CO} has been improved by the development of new equipment in recent years.[7] Previously the expired gas sample was obtained after a variable volume of expiration to clear the dead space. This sample was then analyzed for CO and tracer gas off-line. Newer equipment utilizes online rapidly responding analyzers that provide a record of expired tracer gas and CO concentrations as a function of inspired and expired volumes throughout the entire study. The record of the expired tracer gas as a function of lung volume allows an accurate measurement of the dead space, indicating the proper point to utilize the CO data to calculate DL_{CO}. While this has little value in normal individuals, it provides more accuracy in determining the point in expiration to sample gas volumes in patients, particularly in those with obstructive lung diseases. This may improve accuracy of DL_{CO} measurements by 8%–15%.[7] Although the current equipment does not use this data for other improvements, the authors of the ERS/ATS standards point out that this will improve the reproducibility of the measurements and may provide estimates of gas mixing and variation of the diffusing capacity throughout the lungs.[7]

UNCERTAINTIES IN INTERPRETATION OF DL_{CO}

As noted previously, DL_{CO} is affected by a number of circumstances. Alveolar P_{O_2} and body position do not present significant problems since a standard inspired P_{O_2} and the sitting position are utilized during measurements in almost all clinical laboratories. Equations to correct for alterations of alveolar P_{O_2} are available if needed. Empirical equations also can adjust the predicted value of DL_{CO} to compensate for anemia or polycythemia.

Variability in cardiac output and the alveolar volume present during the measurement provides more significant problems. The increases in DL_{CO} observed during exercise are the result of increases in cardiac output. Increasing cardiac output together with enlargement of the capillary bed not only increases V_C but also increases Dm because capillary volume and surface area of the alveolar–capillary membrane are related variables. Clinical measurements of DL_{CO} are accomplished under resting conditions, minimizing but not obviating variability in cardiac output. In addition, disease can alter the distribution of blood flow in the lung in patterns that do not match the distribution of diffusive properties. Measurements of pulmonary blood flow and its distribution are not measured in usual clinical laboratories. As a result, the effect of cardiac output on DL_{CO} cannot be appreciated in routine determinations. The only practical alternative is to minimize conditions that might alter cardiac blood flow.

Reduction in alveolar volume by disease is a large potential source of error in interpreting DL_{CO}. Correction for the effect of reduced alveolar volume has been attempted by reporting the ratio of DL_{CO}/VA. However, this attempt to normalize measurements by alveolar volume leads to errors because DL_{CO}/VA does not remain constant as alveolar volume changes. Stam et al.[11] reported values of DL_{CO} and DL_{CO}/VA obtained at several alveolar volumes in normal subjects. They recommend using predicted values of DL_{CO} or DL_{CO}/VA for patients with reduced alveolar volumes equal to values in normal subjects measured at the same reduced alveolar volume. This assumes that disease processes that reduce alveolar volume in patients produce the same changes in DL_{CO} as voluntary reduction in alveolar volume in normal subjects. However, other reports in different clinical conditions suggest that some diseases may not affect DL_{CO} in the same manner as voluntary changes in normal subjects. Uncertainties have led to questions regarding the value of the ratio DL_{CO}/VA.[7,11]

Measurements of Dm_{CO} and V_c can be useful in a carefully controlled research setting, but there is little value of using isolated measurements of these two parameters to aid in diagnosis and clinical management. Calculation of Dm_{CO} and V_c involves both a number of assumptions and extrapolations of data in the literature to a specific clinical setting. Even more cogent is the lack of sufficient data to validate the value of these measurements in clinical practice.

CHAPTER 17

Acid–Base Balance

Stanley Goldfarb

INTRODUCTION

Regulation of $[H^+]$ is of crucial importance for maintenance of normal cellular functions. The normal $[H^+]$ is maintained at about 40 nEq/L. When there is even a small change in the $[H^+]$, intracellular proteins gain or lose H^+ ions resulting in alterations in charge distribution that may affect molecular structure and protein function. The hydrogen ion concentration in bodily fluids is largely regulated by the ratio of the concentrations of carbon dioxide and bicarbonate. This is predicated upon the relationship demonstrated in the Henderson–Hasselbalch equation:

$$\text{pH} = \text{pKa} + \frac{[\text{HCO}_3^-]}{0.03\text{P}_{\text{CO}_2}} \qquad (1)$$

where $\text{pH} = -\log[H^+]$ (the H^+ concentration measured in moles per liter) and $\text{pKa} = 6.10$. The lungs are responsible for modulating arterial P_{CO_2}, whereas the kidneys are primarily responsible for modulating the concentration of bicarbonate in plasma. In concert, these organs maintain a stable extracellular acid–base milieu that is readily assessed by measuring arterial pH.

The normal internal environment is maintained within narrow limits: The arterial blood pH is kept remarkably close to 7.40, the bicarbonate concentration is maintained around 24.5 mEq/L, and the P_{CO_2} is maintained at about 40 mm Hg. Deviations of the pH with accompanying changes in the P_{CO_2} and $[HCO_3^-]$ result in the four major categories denoted in Table 17-1. Metabolic acidosis is characterized by acidemia (pH <7.35) that is due to reduced plasma $[HCO_3^-]$. Metabolic alkalosis is characterized by an alkalemia (pH >7.45) that results from an elevation in the plasma $[HCO_3^-]$. Respiratory acidosis is due to hypoventilation resulting in a net increase in P_{CO_2} (hypercapnia) and a concomitant fall in pH. Respiratory alkalosis is due to primary hyperventilation leading to a fall in P_{CO_2} (hypocapnia) and a rise in pH.

In this chapter, the basic physiologic roles that the kidneys and lungs play in maintaining acid–base balance is reviewed before discussion of their adaptation in primary acid–base disorders. The following section then focuses on clinical application of physiologic concepts in analyzing acid–base problems as encountered by the clinician.

BASIC PHYSIOLOGY OF THE KIDNEY IN ACID–BASE BALANCE

Normal metabolism generates large quantities of volatile acid (CO_2) and nonvolatile acid daily. The complete metabolism of carbohydrates and fats generates 15,000 mmol of CO_2 daily. This leads to acid generation as the CO_2 combines with H_2O to form carbonic acid (H_2CO_3). As the volatile fraction is excreted by the lungs during respiration, acid accumulation does not occur. The nonvolatile or "fixed" fraction is produced at a rate of 1 mEq/kg per day. The major source of the nonvolatile acid fraction is the oxidation of sulfur-containing proteins from the diet to sulfuric acid. If this amount of nonvolatile acid is not excreted, life-threatening metabolic acidosis ensues; therefore, for a normal individual to maintain acid–base balance, 50 to 100 mEq of nonvolatile acid must be excreted daily by the kidneys.

The addition of 50 to 100 mEq of acid requires initial buffering before it can be excreted. Whole-body buffering capacity is composed of interacting buffer systems: the bicarbonate and nonbicarbonate buffers (Buf^-), consisting primarily of hemoglobin, proteins, and phosphates. The sum of the buffer anions $[HCO_3^-]$ and $[\text{Buf}^-]$ is the total buffer base and defines total-body buffering capacity. Since all body buffer systems are in equilibrium, a change in the serum $[HCO_3^-]$ reflects concurrent changes in the other body buffer systems. The importance of bicarbonate in buffering is due to its relationship with CO_2. As H^+ ions are buffered by HCO_3^-, there is a decrease in the $[HCO_3^-]$ and a concurrent increase in the dissolved $[CO_2]$. As the $[CO_2]$ can be excreted by the lungs to maintain a constant $[CO_2]$, this substantially increases the buffering capacity of bicarbonate. Since the kidney plays a major role in controlling the $[HCO_3^-]$ and $[HCO_3^-]$ is easily measured in serum, the HCO_3^- anion is a useful parameter to evaluate the renal response to an acid load.

The H^+ ions released from the dissociation of sulfuric acid are titrated by blood bicarbonate and nonbicarbonate buffers.

$$H_2SO_4 + 2NaHCO_3 \rightarrow Na_2SO_4 + 2H_2CO_3 \rightarrow 2H_2O + CO_2 \qquad (2)$$

Although the added H^+ is excreted via CO_2 elimination by the lungs, this occurs at the cost of depletion of $[HCO_3^-]$. To *replenish* the consumed base, bicarbonate is reabsorbed by the kidneys and returned to the blood. This process does not accomplish the replacement of consumed base, since continuous metabolic production of acid will ultimately decrease the available base present. The process of renal *regeneration* of base requires the urinary excretion of acid or H^+ ions in the absence of any urinary bicarbonate. For every H^+ ion excreted, a bicarbonate is returned to the body. If there is any bicarbonate in the urine, there will be a net gain of H^+. Therefore, the kidney has two major functions in this context: (1) Reabsorption of all the filtered bicarbonate; this takes place primarily in the proximal tubule, and (2) The base consumed by metabolism must be

TABLE 17-1 Patterns of P_{CO_2} and HCO_3 Changes in Acid–Base Disorders

Primary Disturbance	Initial Abnormality	Compensatory Response	Expected Compensation
Metabolic acidosis	Decreased pH, decreased $[HCO_3^-]$	Decreased P_{CO_2}	$P_{CO_2} = 1.5 \times [HCO_3^-] + 8 \pm 2$ (Winter's formula)
Metabolic alkalosis	Increased pH, increased $[HCO_3^-]$	Increased P_{CO_2}	P_{CO_2} increases 0.6 mm Hg per mEq/L rise in $[HCO_3^-]$
Respiratory acidosis	Decreased pH, increased P_{CO_2}	Increased $[HCO_3^-]$	Acute: $[HCO_3^-]$ increases 1 mEq/L per 10 mm Hg rise in P_{CO_2} Chronic: $[HCO_3^-]$ increases 3.5 mEq/L per 10 mm Hg rise in P_{CO_2}
Respiratory alkalosis	Increased pH, increased P_{CO_2}	Decreased $[HCO_3^-]$	Acute: $[HCO_3^-]$ falls 2 mEq/L per 10 mm Hg fall in P_{CO_2} Chronic: $[HCO_3^-]$ falls 5 mEq/L per 10 mm Hg fall in P_{CO_2}

generated in the process of urinary acid excretion; this takes place in the distal portions of the nephron, the distal collecting tubule, and the collecting ducts.

■ Bicarbonate Reclamation

The proximal tubule is responsible for reclaiming 70% to 90% of the filtered bicarbonate. This may occur either by direct bicarbonate absorption at the proximal tubule or via proton secretion into the lumen of the tubule. The latter mechanism appears to be the predominant pathway.[1] Acid excretion across the apical membrane of the proximal tubule occurs by an Na^+/H^+ antiporter (NHE3)[2] and to a lesser extent by a proton pump. The secreted proton enters the tubular fluid and combines with filtered bicarbonate ions leading to carbonic acid formation. Under the influence of carbonic anhydrase, carbonic acid is then split into CO_2 and H_2O. The CO_2 diffuses into the cell where it is rehydrated to carbonic acid and then again split into protons and bicarbonate. The bicarbonate ion exits from the cell through the basolateral membrane into the interstitium via a $3HCO_3/Na$ (NBCe1) symporter, while the proton is secreted into the lumen. The basolateral membrane Na^+/K^+ ATPase antiporter, maintaining a low intracellular sodium concentration, further enhances the NHE3 activity.

In summary, reabsorption of bicarbonate is a cyclic phenomenon and requires carbonic anhydrase and is strictly associated to sodium reabsorption.

Biochemical studies show that total NHE3 and NBCe1 protein abundance are upregulated by chronic respiratory acidosis.[3] However, the main mechanism responsible for the elevation in serum bicarbonate is the increased excretion of titratable acid and ammonium, which are stimulated by persistently elevated P_{CO_2} (Fig. 17-1).[4] It is important to understand that this process reclaims filtered bicarbonate but does not result in a net gain of bicarbonate. At the end of the proximal tubule there is a lowering of the luminal pH from 7.26 to 6.70, and the bicarbonate concentration is lowered from 24 mEq/L to 8 mEq/L.[5] The fluid delivered to the distal tubule is essentially the same with respect to pH and bicarbonate concentration as that which leaves the proximal tubule. The reclamation of the remaining bicarbonate occurs in the thick ascending limb and in the outer medullary collecting tubule. At the collecting tubule, H^+ secretion occurs primarily by an H^+ ATPase pump at the luminal membrane, and bicarbonate entry to the blood is via a Cl^-/HCO_3^- exchanger at the basolateral membrane.[6]

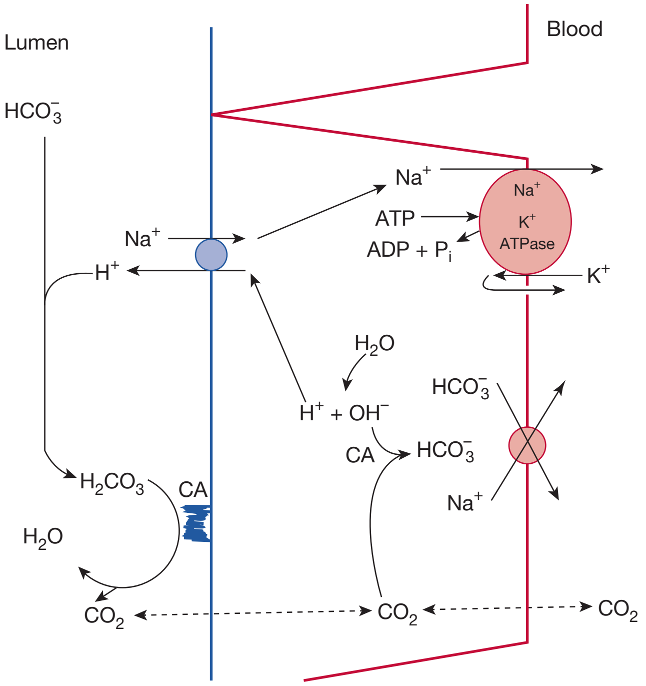

Figure 17-1 Schematic representation of proximal tubular reclamation of filtered bicarbonate. In the lumen, filtered bicarbonate reacts with secreted H^+, generating carbonic acid, which is dehydrated by carbonic anhydrase, CA, located on the brush border. The cell secretes H^+ by a process that exchanges H^+ for filtered Na^+. The source of secreted H^+ is water, which in turn generates OH^- and subsequently bicarbonate because of the presence of intracellular CA. Bicarbonate exits the basolateral side of the cell linked in some fashion with Na^+; sodium is also actively pumped out of the cell.

The crucial role of carbonic anhydrase is demonstrated by the fact that carbonic anhydrase inhibitors, that is, acetazolamide, result in bicarbonate wasting and the generation and maintenance of metabolic acidosis. The most physiologically important regulators of reclamation of bicarbonate are the pH, the P_{CO_2}, and the extracellular volume status of the patient. In states of acidosis, there is enhanced luminal Na^+/H^+ exchange that may be mediated by an increase in intracellular H^+ ions and by increasing the number of new exchangers and increased activity of the Na^+/HCO_3^- cotransporter at the basolateral membrane. Elevation of the P_{CO_2} will promote higher proximal tubular concentration of CO_2 and lead to intracellular acidosis, giving rise to further secretion of H^+ ions and reclamation of bicarbonate. If there is volume depletion, there will be avid Na^+ reabsorption at the proximal tubule in exchange for H^+ and thus greater reabsorption of bicarbonate. Other factors that are important include the luminal bicarbonate concentration, the tubular flow rate, and the serum potassium.

■ Net Renal Acid Excretion

Net excretion of acid occurs primarily in the distal nephron and is largely mediated by the active secretory pumps, H^+-K^+ ATPase and H^+ ATPase. The latter appears to be linked in some way to Cl^- reabsorption to preserve electroneutrality. By definition, to produce net H^+ excretion the secreted H^+ will have to be excreted in processes that do not consume bicarbonate.

To achieve net secretion of protons in the luminal fluid of the distal nephron requires association of the protons with urinary buffers other than bicarbonate. Although secreted protons lower the urinary pH to 4.5 resulting in a 3-pH-unit differential from arterial pH (a 1000-fold increase in H^+ concentration), the quantity of acid excreted as free H^+ is trivial. For example, daily excretion of 2 L of urine with a pH of 5 would result in excretion of only 0.02 mEq of dissociated H^+ ions in contrast to the 50 to 100 mEq of H^+ generated each day from dietary sources. The nonbicarbonate buffers present in the urine that carry out the role of net acid excretion are the titratable buffers, primarily phosphate, which accounts for 40% of net acid excretion, and ammonia, which accounts for the remainder.

The ability of phosphate to act as proton acceptor in the urine is based on its pKa of 6.8. As the urine pH is lowered below the pKa of 6.8, there is conversion of HPO_4^- to H_2PO_4. This transfer continues until the urine pH reaches 5.5, at which point almost all the phosphate present is in the associated form, H_2PO_4. Other components of this system are uric acid (pKa = 5.75) and creatinine (pKa = 4.97). Although the titratable buffers account for a sizable fraction of net basal acid excretion, they cannot increase in amount to enhance acid excretion in settings of acid loading since phosphate excretion depends on phosphate intake and not on synthesis as is the case for ammonia excretion.

The rate of ammonium (NH_4^+) production and excretion can, however, be varied according to physiologic needs. Ammonia (NH_3) combines with H^+ to form ammonium, which is trapped in the collecting tubule lumen and excreted in the urine. The pKa for

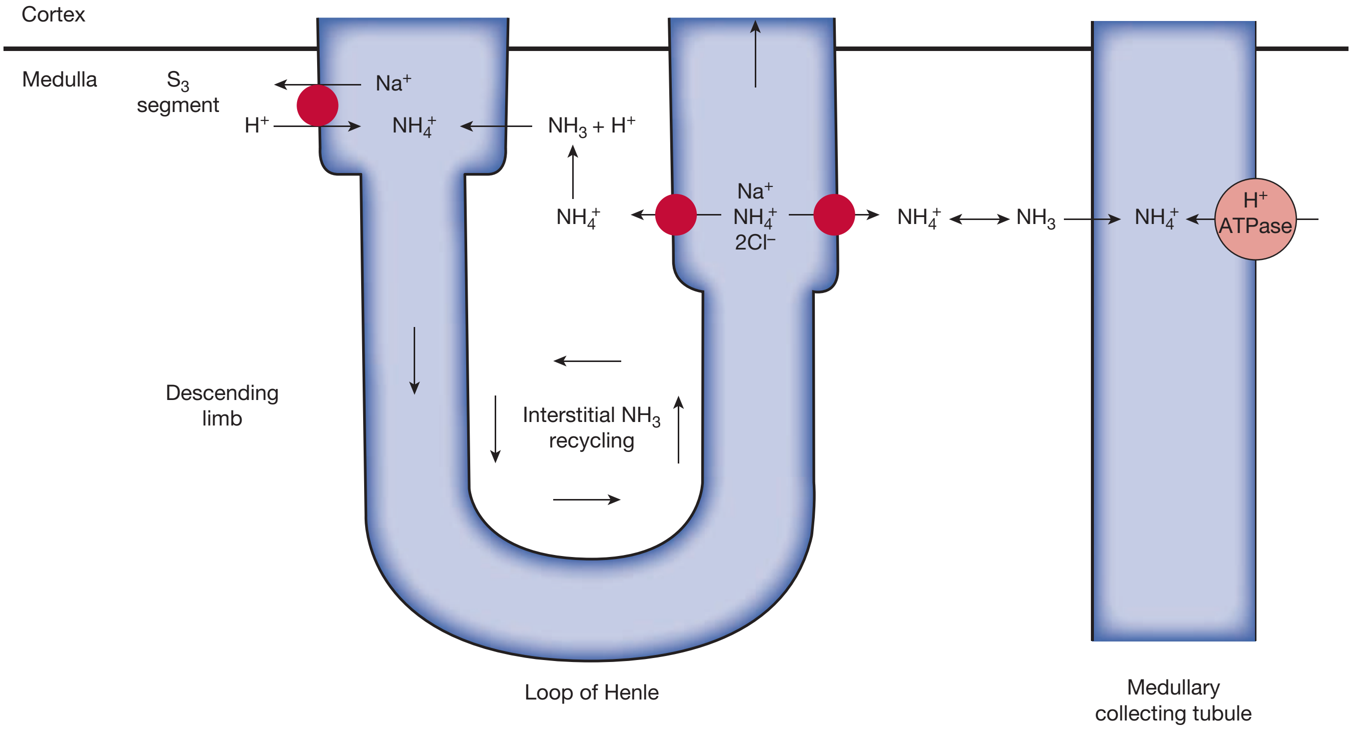

Figure 17-2 Schematic representation of ammonia recycling within the renal medulla. Although NH_4^+ production occurs predominantly in the proximal tubule, most of the NH_4^+ is then reabsorbed in the thick ascending limb, apparently by substitution for K^+ on the Na^+-K^+-$2Cl^-$ carrier in the luminal membrane. Partial dissociation into NH_3 and H^+ then occurs in the less acid tubular cell. The NH_3 diffuses into the medullary interstitium, where it reaches relatively high concentrations; it then diffuses back into those segments that have the lowest pH and therefore have the most favorable gradient: the S_3 segment of the late proximal tubule and, more important, the medullary collecting tubule, where the secreted NH_3 is trapped as NH_4^+ and then excreted. *(Reproduced with permission from Rose B. Clinical Physiology of Acid-Base and Electrolyte Disorders, 4th ed. New York, NY: McGraw Hill; 1994.)*

this reaction is 9.0. The majority of ammonia is synthesized in the proximal tubular cell by the enzymatic breakdown of glutamine. Glutamine is actively taken up by the proximal tubule at the apical and basolateral membranes and transported to mitochondria.[1] Deamidation by glutaminase forms ammonium and glutamate. The latter is further metabolized by glutamate dehydrogenase to form ammonium and α-ketoglutarate. Metabolism of α-ketoglutarate to bicarbonate in the liver leads to return of bicarbonate to the systemic circulation (Fig. 17-2).

The ammonium that is formed is transported into the proximal tubular lumen via the Na^+-H^+ antiporter, working in this case as an Na^+–NH_4^+ antiporter. The ammonium is then reabsorbed in the thick ascending limb by substitution of NH_4^+ for K^+ on the Na^+–K^+–$2Cl^-$ carrier. The intracellular ammonium in the thick ascending limb cell is then dissociated into ammonia and H^+. The ammonia accumulates in the medullary interstitium and is finally secreted into the lumen of the medullary collecting tubule. At this site, due to the low lumen pH (4.5–5) the ammonia accepts an H^+ and is trapped in the lumen and excreted in the urine as NH_4Cl.

The importance of the ammonia system is that it can be regulated by the systemic acid–base state. An acid load initially leads to an increase in ammonium excretion within 2 hours due to formation of a more acidic urine, which enhances ammonia diffusion into the lumen at the collecting duct. After 5 to 6 days there is maximal NH_4^+ excretion due to increased glutamine uptake and enhanced activity of phosphate-dependent glutaminase and glutamate dehydrogenase to produce more ammonium in the proximal tubule.[6] This is presumably mediated by intracellular acidosis of the proximal tubular cell. The net effect is that NH_4^+ excretion can increase from about 30 mEq/d to as much as 300 mEq/d in severe metabolic acidosis. The plasma potassium is an important regulator of ammonia synthesis, as hyperkalemia will result in a transcellular influx of K^+ in exchange for H^+ resulting in lowering of the intracellular H^+ concentration, thus causing an intracellular alkalosis with consequent inhibition of ammonia synthesis. Hypokalemia would have the opposite effect. Urinary acidification also is very important, since an inability to lower urinary pH will result in a reduction in NH_3 trapping in the collecting duct lumen and a subsequent inhibition of the degree of ammonium formation. Inadequate acidification of the urine will also inhibit H_2PO_4 formation.

RESPIRATORY CONTRIBUTION TO ACID–BASE BALANCE

The major roles of the lungs in acid–base balance are to excrete the CO_2 produced daily by aerobic metabolism and to compensate for primary metabolic acid–base disturbances by altering the rate and depth of ventilation. The CO_2 generated by the tissues diffuses into the plasma, at the peripheral capillaries, and is present in the blood in three compartments. Part of the CO_2 remains in the gas phase, but the amount is limited by the solubility coefficient of CO_2 (0.03 mM/mm Hg). CO_2 may also react with amino groups of proteins and form carbamino compounds. The majority of the CO_2 is carried within red blood cells.[7] The red cells contain carbonic anhydrase, which hydrates the CO_2 and thus forms carbonic acid, which dissociates to H^+ and HCO_3^-. The protons are buffered by hemoglobin which has an increased affinity for H^+ at the low oxygen tension present in the peripheral capillaries and venous blood. The bicarbonate produced in the red cell leaves the cell in exchange for chloride. This chloride shift is a characteristic response to elevation of CO_2 in the blood resulting in an acute elevation of bicarbonate in exchange for a drop in serum chloride. When the blood enters the pulmonary circulation, the enhanced oxygenation of hemoglobin promotes release of bound H^+. The H^+ and HCO_3^-, via carbonic anhydrase, combine to reform CO_2, which passively diffuses from the blood into the pulmonary interstitium where the CO_2 tension is very low. Subsequently, CO_2 is lost into the alveolar space.

The rate of minute ventilation is controlled by two sets of chemoreceptors: those in the respiratory center in the brain stem and those in the carotid and aortic bodies located at the bifurcation of the carotid arteries and in the aortic arch, respectively. The central chemoreceptors are stimulated by an increase in the P_{CO_2} or by metabolic acidosis, both of which appear to be sensed by a fall in the pH of the surrounding cerebral interstitial fluid. The peripheral chemoreceptors are primarily stimulated by hypoxemia, although they may also respond to acidemia. The level of alveolar or effective ventilation varies in accord with the total minute ventilation. Level of total ventilation changes as a function of metabolic demand. Under normal circumstances, P_{CO_2} is well controlled between 38 and 42 mm Hg according to the relationship:

$$P_{CO_2} = \frac{\dot{V}_{CO_2}}{\dot{V}_A} \qquad (3)$$

where $\dot{V}_{CO_2}$ is CO_2 production (reflecting metabolic rate) and $\dot{V}_A$ is alveolar ventilation (reflecting CO_2 clearance).

Under basal conditions the volatile acid production or CO_2 that is metabolically generated is completely eliminated by the lungs. The mechanism of the central stimulation of respiration in response to an elevated CO_2 is a topic of intense debate and will not be focused upon in this section (see further details in Chapter 11). However, intracranial adjustments to pH have been consistently observed and have interesting parallels to the effects of acidosis on the proximal tubular cell in the kidney. Increased concentrations of CO_2 in the cerebrospinal fluid (CSF) result in intracellular acidosis, an increase in CSF bicarbonate concentration, and an equimolar reduction in CSF chloride concentration.[7] As brain cells increase their bicarbonate concentration, there is increased buffering, and intracellular brain pH is returned toward normal. The major group of cells within the central nervous system (CNS) responsible for acid–base regulation are the glial cells and the cells of the choroid plexus.[7,8] These cells contain carbonic anhydrase,[9] which converts intracellular CO_2H_2O to H^+ and HCO_3^-. The H^+ is exchanged for Na^+ on the blood side, allowing the intracellular pH to increase. The administration of acetazolamide into the cerebral ventricles blocks the expected increase in CSF bicarbonate in response to hypercapnia.[8] In addition to changes in bicarbonate concentration in the CSF in response to hypercapnia, there are also changes in the levels of ammonia.[10] Brain and CSF ammonia increase in hypercapnia; ammonia acts to enhance H^+ buffering thereby preventing a fall in the bicarbonate concentration.

ACUTE AND CHRONIC ADAPTATION TO RESPIRATORY ACIDOSIS

Figure 17-3 depicts the acute steady-state relationships among P_{CO_2}, plasma bicarbonate concentration, and plasma hydrogen concentration during graded degrees of acute hypercapnia.[11,12] These observations were obtained by sequentially exposing unanesthetized normal human volunteers to increasing concentrations of inspired carbon dioxide in a large environmental chamber. Increasing degrees of hypercapnia are associated with a curvilinear rise in plasma bicarbonate concentration, with higher levels of P_{CO_2} resulting in lesser incremental changes in bicarbonate concentration. This acute rise in bicarbonate is largely due to the chloride shift as described earlier. As a result of the modest increment in bicarbonate, the average rise in plasma $[H^+]$ is limited to 0.75 nEq/L per mm Hg rise in P_{CO_2} rather than the 1-nEq/mm Hg rise that would have occurred if the plasma bicarbonate concentration did not change.[13]

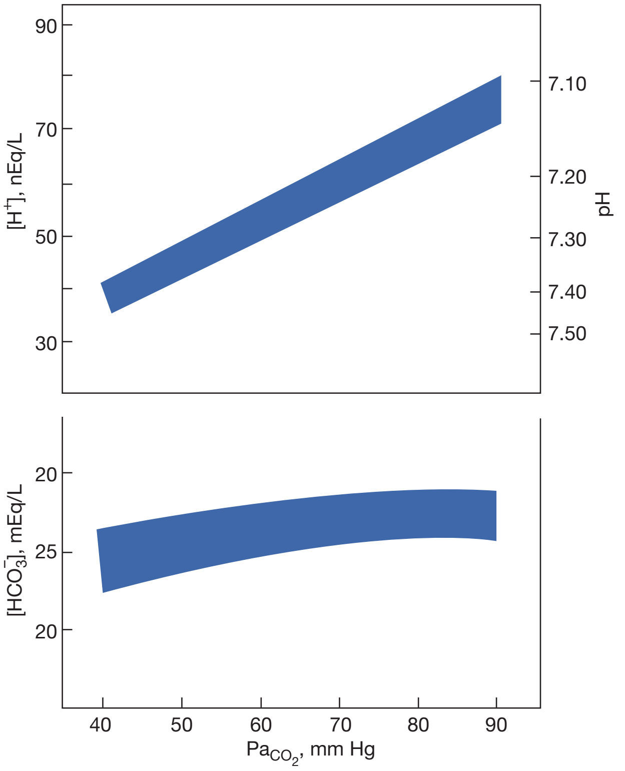

Figure 17-3 Ninety-five percent confidence bands for plasma hydrogen ion and bicarbonate concentrations during acute hypercapnia in normal humans. *(Adapted with permission from Brackett NC Jr, Cohen JJ, Schwartz WB. Carbon dioxide titration curve of normal man. Effect of increasing degrees of acute hypercapnia on acid-base equilibrium. N Engl J Med. 1965;272:6–12.)*

The quantitative aspects of the adaptive response to acute hypercapnia are influenced markedly by the baseline acid–base status. Acute hypercapnia induces a larger increment in both plasma bicarbonate and H^+ ion concentrations in animals with pre-existing hypobicarbonatemia (whether from metabolic acidosis or from chronic respiratory alkalosis) than in animals with pre-existing hyperbicarbonatemia (whether from metabolic alkalosis or from chronic respiratory acidosis).[14] This points out that the factor controlling the amount of bicarbonate generated from an acute rise in P_{CO_2} is not only the initial pH but also the initial bicarbonate concentration. Although the rise in bicarbonate in response to hypercapnia limits the fall in pH acutely, to excrete the gain of H^+ produced from the rise in P_{CO_2} requires renal compensatory mechanisms.

During the initial period of respiratory acidosis, renal compensation takes about 3 to 5 days, during which time there is enhanced reabsorption of proximal tubular bicarbonate, enhanced secretion of H^+, and increased ammonia production.[15]

These processes will lead to an increase of the serum bicarbonate concentration and a rise in the systemic pH toward normal. However, when a steady state is achieved and a stable P_{CO_2} is present, there is no longer an increase in ammonia production. As filtered bicarbonate is increased, there is enhanced proximal secretion of H^+ and a normalization of intracellular pH removing the stimulus for ammonia synthesis.[15]

RENAL ADAPTATION TO RESPIRATORY ALKALOSIS

The adaptive responses to respiratory alkalosis occur in two distinct steps, in close analogy with respiratory acidosis. Hypocapnia reduces the carbonic acid concentration and causes a prompt fall in H^+.[16] Acutely, this alkalemia is ameliorated by a secondary, adaptive reduction in plasma bicarbonate concentration that stems principally from titration of nonbicarbonate body buffers.[17] During protracted hypocapnia, renal adaptive mechanisms yield a further and larger secondary reduction in plasma bicarbonate that results in still greater amelioration of the alkalemia.[17]

In acute uncomplicated respiratory alkalosis the plasma bicarbonate concentration falls by approximately 0.2 mEq/L for each mm Hg reduction in P_{CO_2}. Thus, a reduction in plasma bicarbonate of 3 to 4 mEq/L occurs within minutes after P_{CO_2} is lowered to 20 to 25 mm Hg. The resulting change in plasma H^+ concentration is approximately 0.75 mEq/L for each mm Hg fall in P_{CO_2}, similar to the relationship between P_{CO_2} and H^+ in acute hypercapnia.

When hypocapnia persists beyond the acute phase, the additional decrement in plasma bicarbonate concentration is a consequence of renal adaptive responses and reflects a damping of hydrogen ion secretion by the renal tubule.[5] As a result, a transient suppression of net acid excretion occurs, largely manifested by a fall in ammonium excretion and by an increase in net bicarbonate excretion. These changes lead, in turn, to a positive hydrogen ion balance and a reduction in the body's bicarbonate stores. Persistence of the resulting hypobicarbonatemia is explained by the continued inhibition of tubular hydrogen ion secretion and suppression of bicarbonate reabsorption.

The adaptive retention of acid during chronic hypocapnia is normally accompanied by a loss of sodium into the urine; the resultant decrease in the extracellular volume promotes chloride retention and the typical hyperchloremia of chronic respiratory alkalosis.[18] Upon reaching a new steady state, the net excretion of acid returns to control levels, and the altered anionic concentration of the extracellular fluid (ECF), namely hypobicarbonatemia and hyperchloremia, is maintained by a reduced bicarbonate reabsorption and enhanced chloride reabsorption. On average, the combined effect of cell buffers and renal compensation results in a new steady state in which the plasma HCO_3^- concentration falls approximately 4 mEq/L for each 10-mm Hg reduction in the P_{CO_2}.[19] The renal adaptation to persistent hypocapnia appears to be mediated by some direct effect of P_{CO_2} itself, not the systemic pH. In animals in which plasma bicarbonate was reduced by HCl loading prior to adaptation to sustained hypocapnia, the renal response to a primary reduction in P_{CO_2} was the same as in normal individuals, even though the net effect of this adaptation was an overt fall in pH.

RESPIRATORY ADJUSTMENT TO METABOLIC ACIDOSIS

Metabolic acidosis stimulates both central and peripheral chemoreceptors to increase alveolar ventilation and decrease P_{CO_2} to limit the fall in pH. Although peripheral chemoreceptors appear to play a small role, in animal experiments the same degree of respiratory compensation occurs with intact and with ablated peripheral chemoreceptors. The increase in ventilation begins within 1 to 2 hours and reaches its maximal level at 12 to 24 hours. The stereotype is Kussmaul breathing in acute diabetic ketoacidosis, in which tidal volume is characteristically large with minute ventilation increasing by as much as 35 L. On average, studies in otherwise normal patients with metabolic acidosis reveal that the P_{CO_2} will fall 1.2 mm Hg for every 1.0-mEq/L reduction in plasma HCO_3^- down to a minimum P_{CO_2} of 10 to 15 mm Hg.[20]

On the other hand, failure to mount the expected ventilatory response to metabolic acidosis is an important indicator of respiratory decompensation. Daniel et al.[21] in 140 critically ill trauma patients with metabolic acidosis applied the traditional formula derived from patients with chronic metabolic acidosis. Those whose Pa_{CO2} exceeded the predicted Pa_{CO_2} by 2 mm Hg or more were 4.2 times more likely to be intubated and compensation status was an independent predictor of intubation as early as 60 minutes after episodes of significant hypotension.

RESPIRATORY ADJUSTMENT TO METABOLIC ALKALOSIS

The development of metabolic alkalosis is sensed by the respiratory chemoreceptors resulting in a decline in alveolar ventilation and an elevation of the P_{CO_2}. On average, the P_{CO_2} rises 0.7 mm Hg for every 1.0-mEq/L increment in the plasma HCO_3^- concentration.[18] Values significantly different from the predicted value represent superimposed respiratory acidosis or alkalosis. However, it is unclear whether this response significantly protects the pH from rising. In experimental animals, the rise in P_{CO_2} in metabolic alkalosis increases net H^+ excretion leading to an increase in the HCO_3^- concentration. The effect after several days is that the arterial pH is the same as it would have been if there had been no respiratory compensation.[6,18]

Ventilation may be strongly affected by influences other than acid–base balance. Among these influences are body temperature, increases in circulating catecholamines, changes in cerebral blood flow, changes in systemic blood pressure, and changes in metabolic activities of different organs (e.g., liver), as well as the physiologic state of the lung itself. Perhaps for teleologic reasons, the defense of chronic metabolic acid–base imbalances by ventilatory compensation is not of major importance.

ALTERNATIVE CONCEPTS OF ACID–BASE BALANCE

The preceding discussion has tacitly assumed that the systemic pH is the final control that affects the renal and respiratory response to an acid–base disorder; however, this issue is certainly not settled. The proximal tubular cell of the kidney can often have effects that are more predictably based on the P_{CO_2} rather than the arterial pH. If P_{CO_2} is elevated, the proximal tubular cells act to secrete protons and reabsorb bicarbonate whether or not there is systemic alkalosis or acidosis. This may be explained if an elevation in P_{CO_2} results in intracellular acidosis and the cell is responding appropriately to its internal milieu.[6,18] Similarly, in the central control of respiration, it is controversial as to whether it is CSF pH, interstitial pH, P_{CO_2}, or the bicarbonate concentration that stimulates compensatory changes in ventilation.[7]

In addition to the previously mentioned observations, it is also known that changes in salt and water balance may affect acid–base status. For example, Schwartz's group[18] found that a low dietary sodium chloride intake in dogs with a stable amount of water intake results in hypoventilation, increased P_{CO_2}, and increased HCO_3^- concentration. Studies in dogs have demonstrated that increasing dietary NaCl with a fixed water intake increases the acidity of body fluids, whereas decreasing the NaCl in diet with a fixed water intake decreases the acidity of body fluids.[22]

An alternative view to understanding acid–base disorders and the regulatory response of the lungs and kidneys is offered by the theories initially proposed by Stewart.[23,24] Based on physicochemistry, Stewart emphasized the important principle that H^+ and HCO_3^- as well as the acidic and anionic forms of weak acids are actually dependent variables in a solution. The three independent variables, P_{CO_2}, the strong ion difference (SID), and the total weak anion concentration, can be manipulated externally and serve to determine the concentration of the dependent variables, H^+ and HCO_3^-. The major components of the weak anions in plasma are the albumin and inorganic phosphate concentrations. The SID is the difference between the sums of all strong cations and all strong anions:

$$[\mathrm{SID}] = [\mathrm{Na}^+] + [\mathrm{K}^+] + [\mathrm{Ca}^{2+}] + [\mathrm{MG}^{2+}] - [\mathrm{CL}^-] - [\text{Other Strong Anions}] \qquad (4)$$

This equation is based on the principles of: (1) electroneutrality, (2) dissociation equilibria of all incompletely dissociated substances, and (3) conservation of mass. This concept appears to better explain the basis for renal and ventilatory response in a variety of states, which also affects acid–base balance. Practically, it is observed that the plasma SID is regulated primarily by the kidneys, whereas the P_{CO_2} is regulated by alveolar ventilation. The weak anion concentration is generally not regulated and may often be assumed to be stable.

This concept has primarily been used by investigators in relation to the study of central regulation of ventilation.[7] As albumin and other proteins are not present in the CSF, it is the SID and P_{CO_2} that determine the concentration of weakly dissociating electrolytes, H^+, OH^-, and HCO_3^-. In analyzing various acid–base disturbances, it appears that the change in CSF SID can predict the concentration of CSF bicarbonate.[7]

In evaluating acid–base balance in many species, there is a consistent inverse relationship between the pH and body temperature, whereas the CO_2 content remains stable.[4,25] To explain this relationship Reeves and his coworkers provided evidence that the imidazole ring structure of histidine is responsible for the pH–temperature relationship.[26] This is because imidazole has a pKa in the physiologic range (7.00), is relatively ubiquitous, and has total energy of ionization (7 kcal/mol). To integrate acid–base regulation with receptor function and control of respiration, Reeves and Rahn[4] have proposed the hypothesis that it is not the arterial or intracellular pH that is being regulated per se but rather the constancy of the fractional dissociation of the imidazole moiety of histidine contained in proteins throughout the body.

α-Imidazole is defined as the ratio of the absolute amount of unprotonated imidazole (Im) to total imidazole (HIm + Im):

$$\alpha\text{-Imidazole} = \frac{\text{Im}}{\text{HIm} + \text{Im}} \tag{5}$$

α-Imidazole regulation (alphastat regulation) would have the effect of maintaining cellular protein charge states and enzymatic functions constant. It would also maintain the OH^-/H^+ ratio constant in all compartments. There is also evidence that alphastat regulation directly influences ventilatory status. For example, application of an imidazole blocker to the chemosensitive area of the medulla in cats blocked increases in ventilation caused by local application of acid.[27] Thus, changes in P_{CO_2}, reflecting alveolar ventilation, may be determined by alphastat regulation, which maintains the OH^-/H^+ ratio constant in membranes of the cells in the chemosensitive areas of the medulla.

The difficulty with using these concepts lies in the practical measurement of the relevant molecules. For example, although the imidazole moiety of histidine is considered the most important of the intracellular buffers,[26] its pKa and total energy of ionization may vary widely due to the influence of the local configuration of molecules into which they are incorporated. Thus, even in lower animals such as fish under different temperatures, calculations based on the alphastat model do not accurately predict the acid–base disturbance, since the pKa and enthalpy of ionization vary with temperature and are difficult to measure.

Similarly, measurement of the plasma SID is problematic and is often replaced by the "SID effective," which is roughly equal to the bicarbonate concentration plus albumin and inorganic phosphate.[23] Calculation of the anion gap (see below) accounts for the roles of the strong ions Na^+ and Cl^- as well as bicarbonate but does not account for the role of inorganic phosphate or plasma proteins. Although the bicarbonate concentration may not be, strictly speaking, an independent variable, the AG calculation does indicate the quantity of unmeasured anions and hence is an indirect measure of the SID. If one considers the impact of serum proteins and inorganic phosphate in the unmeasured anion pool, the AG gives a very useful parameter in evaluating acid–base disturbances. Many studies have compared the utility of SID versus corrected AG (corrected for the level of serum albumin) and found that it was no more accurate in making a diagnosis. One study of patients in an intensive care unit reported that Stewart's method diagnosed underlying metabolic acidosis in 22 patients (of the total of 152 patients in the study) with normal plasma bicarbonate level. However, when the AG was corrected for hypoalbuminemia, it was elevated in all of the samples with normal bicarbonate showing the effectiveness of the traditional approach.[28] In another study of 935 ICU patients, the Stewart method detected metabolic acidosis in 14% patients with normal bicarbonate levels, whereas the traditional method made a similar diagnosis in 13% of patients.[29] A recent study in patients with septic shock and liver transplantation found an excellent correlation between SID and corrected AG.[30]

Thus, as will be described in more detail in the following section, the use of the AG is still the most clinically useful tool to determine the contribution of different metabolic etiologies of metabolic acidosis.

APPROACH TO PATIENTS WITH AN ACID–BASE DISTURBANCE

In this section, a diagnostic approach to disorders of acid–base balance is outlined, with a particular emphasis on the ventilatory response and its role in mitigating or exacerbating acid–base disorders. The approach to the patient with complex acid–base disorders also is reviewed.

Analysis of Clinical Information

Table 17-1 summarizes the pattern of abnormality of arterial blood acid–base parameters in the four classic acid–base disorders. It also indicates the physiologic or compensatory response induced in pulmonary or renal function in response to the initial disturbance.

Base Excess and Base Deficit Notations

Base excess and *base deficit* are terms applied to an analytic method for determination of the appropriateness of responses to disorders of acid–base metabolism.[31] The base excess or deficit is determined by measuring blood pH against ambient P_{CO_2} and against a P_{CO_2} of 40 mm Hg. If the calculated HCO_3^- is below 25 when the P_{CO_2} is 40 mm Hg and the original pH is low, a base deficit is indicated. The magnitude of the deficit is expressed as the number of mEq of bicarbonate needed to restore the serum bicarbonate to 25 mEq/L at a P_{CO_2} of 40 mm Hg compared to that at the ambient P_{CO_2}. The use of notations for base excess and deficit has been debated in the medical literature. This notation is favored in the evaluation of acid–base status in the operating room because acute changes in P_{CO_2} and in HCO_3^- can be simply evaluated by this approach. However, this notation can be misleading in chronic respiratory alkalosis or acidosis, since the patient with chronic respiratory alkalosis will be categorized as suffering from a base deficit because of the low serum bicarbonate induced as compensation for the reduced P_{CO_2}. In fact, a "base deficit" is a normal physiologic response to the chronic reduction in P_{CO_2}. Unfortunately, lack of familiarity with the complete analytical paradigm used for this analysis of acid–base disorders has led some to focus on the designations "base deficit" and "base excess" as guides to bicarbonate or acid therapy in chronic respiratory disorders. In addition, discrepancies between the buffering characteristics of plasma, blood, and whole body have also been cited as potential weaknesses in a system for assessing acid–base disorders that relies on in vitro CO_2 titration methods. We therefore recommend that the physiologic evaluation of the patient be the mode of analysis of acid–base disorders rather than an emphasis on derived formulae.

Use of Nomograms

As indicated earlier, the body buffers and the kidneys respond in a predictable fashion to a change in P_{CO_2}, whereas ventilatory

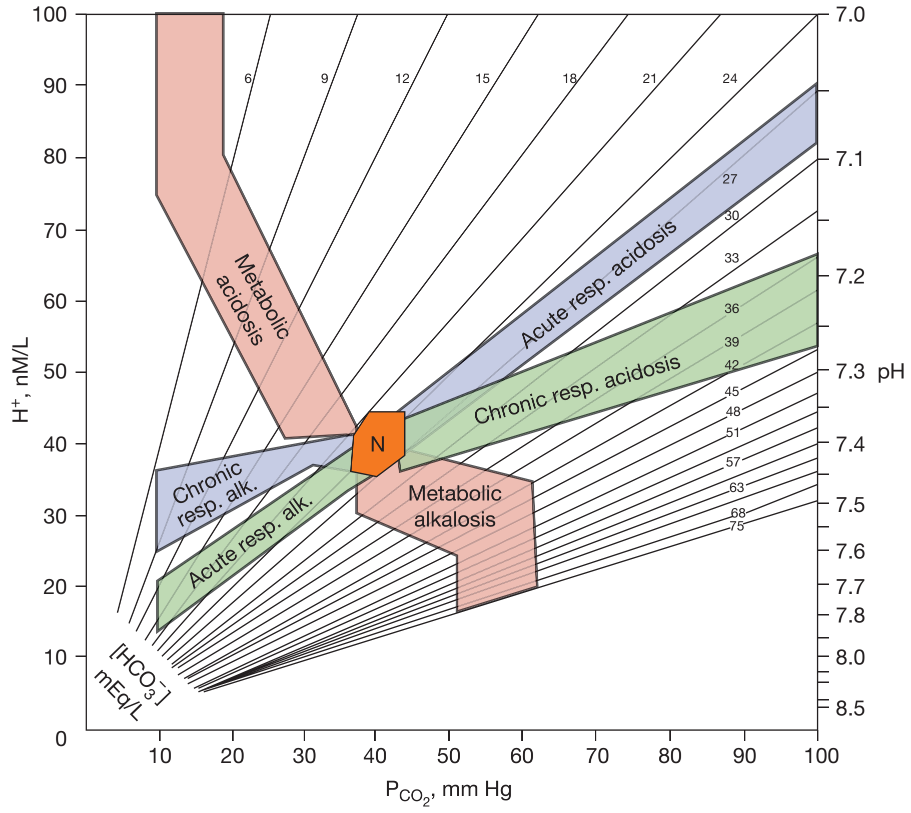

Figure 17-4 Acid–base map showing the normal range (N) and the confidence bands for acute or chronic respiratory and metabolic acid–base disturbances. The ordinates are the partial pressure of CO_2 and the hydrogen-ion activity given in nmol/L and pH units. Isopleths for bicarbonate concentration, in mEq/L, are also shown. *(Reproduced with permission from Goldberg M, Green SB, Moss ML, et al. Computer-based instruction and diagnosis of acid-base disorders. A systematic approach. JAMA. 1973;223(3):269–278.)*

response to changes in [HCO_3^-] also is predictable. Also, the resulting changes in bicarbonate and pH are time dependent so that a larger change occurs in several days than in the first hours. The confidence bands for changes in P_{CO_2} or HCO_3^- in response to primary disturbances are shown in Fig. 17-4.[7] Any deviation can be interpreted as a reflection of processes other than a compensatory response. For example, in a patient with chronic obstructive airways disease, other factors affecting the acid–base status are the concentration of potassium in the plasma, the size of ECF volume, chloride depletion, diuretics, renal hypoperfusion, and coexisting renal disease. The special case of posthypercapnic alkalosis is discussed in the next section.

In evaluating an acid–base disorder, the history and physical examination are invaluable in focusing attention on potential pathologic processes.[32] The composition of blood, with respect to serum electrolytes and blood gases, is then examined for consistency with clinical impressions. However, in using the acid–base map (Fig. 17-4), remember that the map is based on data from individuals who had a single disorder. Therefore, the map does not take into account the possibility of multiple disorders. For example, in a patient with chronic obstructive airways disease whose sputum has turned purulent and who develops nausea and vomiting, the possibility arises of coexistent metabolic alkalosis and acute respiratory acidosis. However, ill-advised application of the arterial blood-gas values from this patient (e.g., pH = 7.25 and $P_{CO_2} = 75$ mm Hg) to the acid–base map would lead to the erroneous conclusion that a chronic respiratory acidosis is present. Thus, the clinician needs to integrate laboratory data with clinical assessments to properly analyze clinical disorders of acid–base balance.

■ Approach to the Patient with Metabolic Acidosis

An increase in the H^+ concentration of the ECF will result in a series of predictable responses that allow the clinician to ascertain the appropriateness of organized homeostatic responses to the perturbation.[20] The pathophysiologic basis for the initiation of metabolic acidosis and homeostatic responses in the defense of systemic pH have been defined earlier in descriptions of the buffering of newly introduced acid [see Equation (1)] and in the demonstration of the normal confidence band for the ventilatory response to metabolic acidosis as detailed in the acid–base nomogram (Fig. 17-4).

A key clinical distinction in the pathogenesis of metabolic acidosis is whether the production of the acidosis is rapid or slow. If the etiology of the metabolic acidosis is merely the continued ingestion of a diet that generates a variety of fixed acids such as H_2SO_4 [see Equation (2)] from the metabolism of methionine residues, then the serum HCO_3^- will fall slowly as only that fraction of the 50 to 100 mEq of H^+ generated from diet that is not excreted would be added to the body fluids each day. However, if the addition occurs because of an acute increase in the acid load such as may occur with lactic acidosis, the kidney capacity can be rapidly overwhelmed, and serum bicarbonate may fall precipitously. See Table 17-2 for the common causes of metabolic acidosis.

Utility of the Anion Gap

As seen in Equation (6), the buffering of mineral acids will result in the production of the salt of the acid, NaA.

$$\mathrm{NaHCO_3 + HA \rightarrow NaA + H_2CO_3^- + H^+ \rightarrow CO_2 + H_2O + NaA} \quad (6)$$

If the kidney is able to excrete this salt or, in the case of the production of the salts of organic acids such as lactic acid, if the liver can metabolize the anion to HCO_3^-, then there will be no accumulation of the anion in the ECF. Typically, anions associated with strong organic acids are not measured with routine electrolyte determinations and contribute to the so-called anion gap (AG). Determination of the plasma AG is primarily used in the differential diagnosis of metabolic acidosis. However, the AG also changes in other conditions, a finding that may be of diagnostic importance.

TABLE 17-2 Causes of Metabolic Acidosis (Common)

Failure to generate new bicarbonate to replace that consumed in buffering dietary acid load
Diminished NH_4^+ production and excretion
Reduced renal mass
Chronic hyperkalemia
Chronic aldosterone deficiency
Decreased H^+ ion secretion (primary)
Distal renal tubular acidosis
Increased H^+ ion production
Lactic acidosis
Ketoacidosis
Toxic ingestion
Bicarbonate or equivalent losses from body fluids
Renal–proximal RTA, carbonic anhydrase inhibitors
GI—diarrhea, villous adenoma, fistula

The plasma AG is calculated from the following formula based on routine laboratory determination[33]:

$$AG = (\text{cations}) - (\text{anions})$$

Since Na^+ is the primary measured cation and Cl^- and HCO_3^- are the primary measured anions:

$$AG = [Na^+] - ([Cl^-] + [HCO_3^-]) \qquad (7)$$

The normal value is 12 ± 2 mEq/L.

An increase in the AG can be produced by an increase in unmeasured anions or by a reduction in unmeasured cations. Hypokalemia, hypocalcemia, or hypomagnesemia can only raise the AG by a few mEq/L, since these ions can only deviate from normal by a mEq/L or less and maintain a physiologic condition. The predominant extracellular unmeasured anion is actually albumin with many negative charge sites per molecule. Hence, a mild elevation in the AG can occur in conditions in which the albumin concentration or the charge characteristics of albumin are altered, for example, in metabolic alkalosis. In that instance, a number of factors may contribute to the increment, including a rise in the plasma albumin concentration due to extracellular volume depletion and contraction of plasma constituents, an increase in the number of negative charges per albumin molecule induced by the rise in extracellular pH titrating protons off the albumin molecule, and a tendency for systemic alkalemia to induce an increase in lactate production. This latter response serves a homeostatically beneficial function.

In forms of metabolic acidosis in which there is buffering of excess hydrochloric acid by extracellular bicarbonate, then

$$HCl + NaHCO_3 \rightarrow NaCl + H_2CO_3 \rightarrow CO_2 + H_2O \qquad (8)$$

Bicarbonate is replaced on an equimolar basis by chloride, and there is no change in the AG; this disorder is also called a *hyperchloremic acidosis* because of the rise in the plasma chloride concentration. Both diarrhea and type 2 (proximal) renal tubular acidosis can lead to the loss of $NaHCO_3$. The kidneys compensate by retaining NaCl in an attempt to preserve volume, with the net effect being a mEq-for-mEq exchange of chloride for bicarbonate.

If the retained acid is not HCl but an organic acid whose anion is not routinely measured such as lactic acid, then the increase in the unmeasured lactate anion will raise the AG. It is important to emphasize that the acidosis is due to the retained proton; the anion is irrelevant to the change in acid–base status or systemic pH but is important as a diagnostic tool. The major causes of a high-AG metabolic acidosis include those listed in Table 17-2 under disorders of increased H^+ production. Although renal failure produces an acidosis because of failure of H^+ excretion and bicarbonate production, most patients with severe renal failure retain both hydrogen and anions, such as sulfate, phosphate, and urate and, hence, demonstrate a high AG.

The diagnostic utility of a high AG is greatest when the AG is above 20 mEq/L; in this setting, renal failure, lactic acidosis, or evidence of a toxic ingestion will almost always be present. When the AG is less than 20 mEq/L, identifying the anions that contribute to the mild elevation[33] is often impossible.

Urine AG

Estimation of the urinary ammonia content may be a useful clue to the etiology of metabolic acidosis, as the value will increase in diseases in which kidney function affecting acid–base balance is completely intact but in which bicarbonate is lost from the body fluids.[13] The calculation of the urinary AG is shown in Equation (9):

$$\text{Urine AG} = (\text{Urine }[Na^+] + \text{Urine }[K^+]) - \text{Urine }[Cl^-] \qquad (9)$$

The usual value will be negative, between −25 and −50 mEq/L, as the ammonium content of the urine is typically in this range, and ammonium accounts for the apparent discrepancy between the level of cations and anions in the urine. In states of metabolic acidosis due to diarrhea or to chronic acid ingestion, the value will be >50 mEq/L as ammonium production is stimulated.

In some conditions, the urine AG will be very low or even positive in the face of metabolic acidosis. In all forms of renal insufficiency, ammonia production by the kidney will be deficient and significantly contribute to a reduced urinary AG and to metabolic acidosis. In type I distal RTA, inability to maintain a steep gradient for protons in the distal tubular lumen and in the collecting duct results in a deficiency in ammonia trapping in the luminal fluid and therefore a decreased excretory rate for ammonia. This in turn leads to metabolic acidosis, a low ammonia excretion, and an abnormally low urinary AG. Finally, type IV RTA, a condition in which hyperkalemia and mild renal insufficiency are found, hyperkalemia suppresses renal ammonia production, and a low urinary AG is found.

In any condition associated with hypokalemia, increased intracellular proton accumulation (which results from the exchange of cellular potassium for extracellular protons) will lead to an exaggerated ammonia production in the kidney. Hence, the use of the AG in the urine will be particularly useful to differentiate classic type I RTA from hypokalemia and acidosis due to diarrhea. The former will show a very low urine AG. Typically, a careful history will elicit the crucial information, and measurement of the urine AG will be confirmatory.

■ Clinical Assessment of Metabolic Acidosis

In approaching a patient with metabolic acidosis, the clinician should first assess the history and clinical circumstances. For example, patients with renal failure or with uncontrolled diabetes may be presumed to have a metabolic acidosis until disproved by laboratory analysis. The next step is to evaluate the serum electrolytes to determine the level of the serum HCO_3^- and the presence of an AG of greater than 12 ± 2 mEq/L. If both are present, then one must consider the possibility of a metabolic acidosis secondary to increased acid production as listed in Table 17-2. If the HCO_3^- is reduced but the serum AG is normal, then one is dealing with either a respiratory alkalosis or a metabolic acidosis due to reduced renal

TABLE 17-3 Causes of Metabolic Alkalosis

- Contraction alkalosis

capacity to generate replacement HCO_3^- to compensate for that lost as a result of decreased acid excretion or increased HCO_3^- loss.

At this point arterial blood gases should be assessed to determine the pH and the ventilatory response. Finding a low pH establishes the diagnosis of metabolic acidosis. Reference to the acid–base nomogram (Fig. 17-4) will verify whether the clinical response is consistent with a simple metabolic acidosis with a normal ventilatory response or whether some other disturbance in ventilation is present.

■ Approach to the Patient with Metabolic Alkalosis

Two separate processes are involved in metabolic alkalosis: an excess load of base that is generated either endogenously or exogenously (see Table 17-3) and maintenance of an abnormally high concentration of bicarbonate in the plasma.[5] During hypercapnia, the load of base is the result of renal compensation and de novo bicarbonate generation; in posthypercapnic alkalosis, the key abnormality is maintaining the bicarbonate level in plasma at inordinately high levels, as will be discussed below.

Generation of Metabolic Alkalosis

Causes of metabolic alkalosis are predominantly events that remove H^+ ions from the body but also include circumstances in which excess base is added to the body fluids. Hydrogen loss can occur from the gastrointestinal tract or in the urine. Each mEq of hydrogen lost generates 1 mEq of bicarbonate, as the source of hydrogen ions in cells that produce and secrete protons is:

$$H_2O \rightarrow H^+ + OH^- + OH^- + CO_2 \rightarrow HCO_3^- \qquad (10)$$

When vomiting or tube drainage prevents stomach acid from reaching the duodenum and combining with HCO_3^- released from pancreatic secretions, the net balance of bicarbonate in body fluids becomes positive, and serum HCO_3^- begins to rise.

Increased renal acid losses may result from enhanced distal hydrogen secretion. Aldosterone acts both by directly stimulating the secretory H^+ ATPase pump and, via the stimulation of sodium reabsorption, by making the lumen more electronegative, thereby favoring hydrogen ion secretion. Increased distal nephron delivery and reabsorption of sodium further stimulates hydrogen ion secretion as the accompanying anion is less avidly reabsorbed than is sodium, and the lumen of the distal nephron becomes more negatively charged. Excess secretion of mineralocorticoids can lead to metabolic alkalosis by this pathway. In patients treated with loop-active or thiazide diuretics, enhanced distal delivery of sodium and increased secretion of aldosterone are usually present, thereby enhancing renal bicarbonate production as a result of enhanced hydrogen ion secretion. This pattern commonly leads to the development of metabolic alkalosis.

Chronic respiratory acidosis leads to a secondary increase in renal hydrogen secretion, as the subsequent rise in the plasma bicarbonate concentration will restore the pH toward normal as a compensatory response. If the patient undergoes a therapeutic maneuver such as rapid lowering of the P_{CO_2} by mechanical ventilation, a posthypercapnic form of metabolic alkalosis will ensue as the patient is left with an elevated plasma bicarbonate concentration.

Hypokalemia is a frequent finding in patients with metabolic alkalosis and may not only be the consequence of some of the disorders that lead to the initiation of metabolic alkalosis but may also actually induce an alkalotic tendency. Gastric drainage, diuretics, and mineralocorticoid excess all induce potassium as well as hydrogen losses through the GI tract and kidney, respectively. Hypokalemia also induces a transcellular shift in which potassium is exchanged in an electroneutral fashion for hydrogen ions in the ECF. This exchange directly raises the extracellular pH, lowers the intracellular pH, and mitigates the hypokalemia. Intracellular acidosis in renal tubular cells promotes hydrogen secretion and therefore bicarbonate reabsorption (see “Bicarbonate Reclamation,” above).

Administering large amounts of alkali does not maintain metabolic alkalosis in normal individuals because of rapid urinary excretion, but it may induce the initiation stage of metabolic alkalosis if factors are active to sustain a high rate of renal HCO_3^- reabsorption. A form of metabolic alkalosis termed *contraction alkalosis* occurs when there is loss of relatively large volumes of bicarbonate-free fluid. Administration of a loop diuretic to induce rapid fluid removal in a markedly edematous patient is the most common cause of a contraction alkalosis. The plasma bicarbonate concentration rises in this setting because there is contraction of the extracellular volume around a relatively constant quantity of extracellular bicarbonate. The degree to which this occurs is in part minimized by intracellular buffering, as the release of hydrogen ions from cell buffers lowers the plasma bicarbonate concentration toward the baseline value. Even this form of alkalosis is probably critically dependent on increases in renal bicarbonate production for its manifestation, since the diuretics promote excess renal hydrogen ion secretion as noted earlier.

Maintenance Phase of Metabolic Alkalosis

Maintenance of metabolic alkalosis requires an increase in the reabsorption of bicarbonate by the renal tubule.[27] Four factors are known to be important in the maintenance phase of metabolic alkalosis: extracellular volume depletion, chloride depletion, hypokalemia, and mineralocorticoid excess.[34]

A reduction in ECF volume and possibly a fall in the glomerular filtration rate (GFR) secondary to extracellular volume depletion are major stimuli for increasing the proximal reabsorption of bicarbonate. The enhanced proximal tubular bicarbonate reabsorption is likely the most important factor. This reabsorption is stimulated by extracellular volume depletion, which is a frequent accompaniment of metabolic alkalosis. Enhanced proximal tubular reabsorption of sodium ions is a major factor in the enhanced rate of proton secretion, a key factor in the proximal tubular reabsorptive pathway for bicarbonate. Enhanced activity of the sodium–proton exchanger in the luminal membrane of the proximal tubule is an important component of the transport system.

In addition, an important role is played by the distal nephron in maintaining metabolic alkalosis by way of the secondary phenomena of chloride depletion, extracellular volume depletion, and hypokalemia.[35] Cells of the cortical collecting tubule can either reabsorb or secrete bicarbonate depending on homeostatic requirements. For example, during excess bicarbonate ingestion, the secretory process predominates, and excess bicarbonate is lost into the urine. Chloride depletion enhances the bicarbonate reabsorptive pathway by reducing chloride availability at an anion exchange site on the luminal membrane of the type A intercalated cell. This exchange process normally allows bicarbonate entry into the urine in exchange for chloride absorption. Chloride depletion thus blocks bicarbonate loss.

Hypokalemia acts to stimulate bicarbonate reabsorption through several mechanisms. First, loss of potassium from the ECF leads to a shift of protons into the cell as potassium leaves the cell. Hence, intracellular pH falls, driving enhanced tubular bicarbonate reabsorption. Also, severe potassium depletion produces a defect in tubular fluid chloride reabsorption, thus mimicking a chloride depletion state. Finally, excess mineralocorticoid hormone, either as a result of primary overproduction or due to a variety of secondary hyperreninemic states, stimulates H^+ secretion in the cortical collecting tubule and thereby stimulates increased renal tubular bicarbonate production and helps maintain metabolic alkalosis.

Typically, all four components coexist in patients with metabolic alkalosis secondary to vomiting or gastric drainage following gastric intubation. If any of the factors is present in a patient with metabolic alkalosis, therapy will be only partially successful until all the factors have been eliminated.

Depression of ventilation in metabolic alkalosis is a normal physiologic response to the elevation in serum bicarbonate but is difficult to assess clinically and may not be found in many patients as detailed earlier.[36]

Posthypercapnic Metabolic Alkalosis

In response to sustained hypercapnia, the increased excretion of hydrogen ion in the urine and the increased bicarbonate generated by the acid secretory process increase the concentration of bicarbonate in the plasma, as described earlier. During this process, the total sodium content of the body remains stable, as does the ECF volume (unless there is a separate reason for a volume abnormality, e.g., right ventricular failure and the use of diuretics). If correction of hypercapnia occurs, for example, through the use of mechanical ventilation without simultaneous replacement of sodium chloride, the urinary loss of sodium bicarbonate may lag for several hours or days. This is particularly true if there is concomitant depletion of the ECF volume. This leads to an increase in the reabsorption of solute, including sodium bicarbonate, by the proximal tubule, sustaining the high bicarbonate concentration in blood. This process is similar to the maintenance phase of metabolic alkalosis described earlier; the other processes outlined also could pertain to this posthypercapnic state and produce a persistent metabolic alkalosis following correction of hypercapnia.[37]

■ Approach to the Patient with a Mixed Acid–Base Disorder

The approach to patients with mixed acid–base disorders, that is, more than one disturbance in acid–base metabolism, is particularly challenging because no nomogram, calculation of base excess or deficit, or other formula can allow the clinician to parse the pathophysiologic disorders and allow a rational therapeutic plan.[18] Rather, it is the combination of clinical assessment, application of expected compensatory responses, assessment of the AG, and application of principles of physiology that together allow a successful analysis.

To determine the presence of a mixed or complex acid–base disorder, the clinician must follow a rigorous approach that integrates clinical observation with assessment of a variety of laboratory parameters. No single nomogram or other shortcut device will suffice. The initial step is to perform a history and physical examination to seek processes that could contribute to acid–base disorders. For example, any patient who has vomited has the potential for developing a metabolic alkalosis, and any patient with chronic renal failure surely has metabolic acidosis as an ongoing process for which compensation will be necessary. Moreover, many clinical conditions are typically characterized by the presence of more than one concurrent disorder. Patients with severe liver failure will usually experience respiratory alkalosis as a consequence of hepatic encephalopathy so that any other conditions associated with abnormalities of acid–base balance that may develop in these patients will result in mixed acid–base disorders. Septic shock is associated with the mixed disorders of respiratory alkalosis and metabolic acidosis due to lactic acid production. Immediately, following cardiac arrest, patients will have both a respiratory and a metabolic acidosis. Patients with renal failure who undergo gastric drainage will manifest both metabolic alkalosis and metabolic acidosis as a result of the underlying conditions. The clinician must consider these expected abnormalities in acid–base balance when addressing laboratory results.

The second step in the process is to evaluate a venous blood sample for determination of the electrolytes, blood urea nitrogen (BUN), creatinine, and other parameters indicative of liver function. Here, the evaluation of the $[HCO_3^-]$ and analysis of the AG is invaluable. Decrements or elevations of $[HCO_3^-]$ will point toward a disturbance in the body's buffering system. The AG measurement, if elevated, will clarify whether a metabolic acidosis is present, as described earlier. Also, analyzing the AG together with the venous $[HCO_3^-]$ can provide important information. Because the anions that accumulate in most forms of organic acidosis (lactic acidosis, ketoacidosis, many toxic ingestions) can be metabolized in the liver to bicarbonate through the Krebs cycle, adding the unmeasured anion concentration to the current plasma HCO_3^- concentration indicates the level of $[HCO_3^-]$ prior to the onset of the metabolic acidosis.

ILLUSTRATIVE CASES

The following cases illustrate the clinical approach to the patient with acid–base disturbances.

■ Metabolic Acidosis

A 75-year-old patient presented with a 7-day history of intermittent diarrhea and a 5-lb weight loss. The rest of the history was unrevealing. Physical examination only revealed signs of volume depletion. Laboratory values were as follows:

$$[BUN] = 18 \text{ mg/dL}$$
$$[Na^+] = 138 \text{ mEq/L}$$
$$[K^+] = 3.0 \text{ mEq/L}$$
$$[Cl^-] = 110 \text{ mEq/L}$$
$$[HCO_3^-] = 13 \text{ mEq/L}$$

At this point, the lack of an elevated AG (12 mEq/L) and the reduced bicarbonate concentration together suggest the possibility of either respiratory alkalosis or metabolic acidosis of the non-AG variety, that is, in which the chloride concentration has risen as bicarbonate has been utilized in buffering reactions or has been lost from body fluids. The history of diarrhea strongly suggests that a metabolic acidosis is the culprit in the disorder. The relatively low BUN supports the theory that diarrhea, and not renal insufficiency, is the main etiologic factor.

Arterial blood gases are then obtained:

$$pH = 7.24$$
$$P_{CO_2} = 27 \text{ mm Hg}$$
$$P_{O_2} = 100 \text{ mm Hg}$$
$$[HCO_3^-] = 13 \text{ mEq/L}$$

The low serum bicarbonate in association with a low arterial blood pH indicates that the patient has a metabolic acidosis. Finding that the rate of ventilation produces a P_{CO_2} of 27 is consistent with the expected P_{CO_2} of 27.5 ± 2 mm Hg calculated from Winter's formula (see Table 17-1). Reference to the acid–base nomogram (see Fig. 17-4) reveals the graphical equivalent of this calculation as the values for pH, P_{CO_2}, and $[HCO_3^-]$ fall in the confidence band for metabolic acidosis. Other possible etiologies for this form of non-AG metabolic acidosis would include mild renal insufficiency, wherein the decline of GFR has not reached a level where the unmeasured anions such as SO_4^{2-} would begin to accumulate in plasma, and the ingestion of salts such as ammonium chloride which are metabolized in the liver to urea and hydrochloric acid. Urinary electrolyte analysis confirms the diagnosis:

$$\begin{aligned}[Na^+] &= 50 \text{ mEq/L}\\ [K^+] &= 20 \text{ mEq/L}\\ [Cl^-] &= 140 \text{ mEq/L}\\ \text{Urine volume} &= 2 \text{ L}\\ \text{Urinary AG} &= -70 \text{ mEq/L}\end{aligned}$$

The discrepancy between the sum of urine cations and anions in the negative range indicates that an unmeasured cation, in this case ammonium, is being excreted into the urine.[13] It is the excretion of protons in association with ammonia that allows the renal excretion of the accumulated acid load and the attempted regeneration of body HCO_3^- stores. If this value was not greater than −20 to −50 mEq/L, a defect in ammonia production or excretion such as could be found in renal insufficiency or in renal tubular acidosis could be present. In this case, the large urinary cation gap suggests that diarrhea is the culprit.

Metabolic Alkalosis

A 65-year-old patient experienced severe and unremitting vomiting for 4 days. He has had a history of peptic ulcer disease, but he decided to medicate himself with an antacid, which he could not keep from vomiting. There was no other significant past medical history. Physical examination showed a moderate degree of orthostatic hypotension as blood pressure fell from 100/70 mm Hg supine to 90/60 mm Hg when seated. The rest of the examination was not remarkable except for some abdominal tenderness.

Laboratory results revealed the following:

$$\begin{aligned}[BUN] &= 28 \text{ mg/dL}\\ [Na^+] &= 43 \text{ mEq/L}\\ [K^+] &= 3.0 \text{ mEq/L}\\ [Cl^-] &= 85 \text{ mEq/L}\\ [HCO_3^-] &= 39 \text{ mEq/L}\end{aligned}$$

The elevation in HCO_3^- content is consistent with either metabolic alkalosis or with chronic respiratory acidosis with renal compensation. The clinical circumstances strongly imply that metabolic alkalosis will be found, since the patient has been vomiting and has therefore been generating new alkali in the body fluids as gastric hydrochloric acid is lost. Also, the vomiting-induced deficit in ECF volume and in body fluid chloride content will likely act to help sustain the metabolic alkalosis by stimulating a high rate of renal bicarbonate transport by the proximal tubule and inhibiting distal nephron bicarbonate secretion.

Arterial blood gases are then obtained:

$$\begin{aligned}\text{pH} &= 7.52\\ P_{CO_2} &= 46 \text{ mm Hg}\\ [HCO_3^-] &= 36 \text{ mEq/L}\end{aligned}$$

These confirm the diagnosis. Note that the hypoventilatory response is modest, probably because of the degree of hypokalemia, which tends to acidify the intracellular fluid and stimulate ventilation. Correction of this abnormality will require both replacement of fluid with sodium and chloride and adequate intake of potassium to fully restore acid–base balance to normal.

Mixed Acid–Base Disturbance

An insulin-dependent diabetic patient with several days of vomiting developed diabetic ketoacidosis. The following set of electrolytes is obtained:

$$\begin{aligned}[Na^+] &= 140 \text{ mEq/L}\\ [K^+] &= 5 \text{ mEq/L}\\ [Cl^-] &= 90 \text{ mEq/L}\\ [HCO_3^-] &= 15 \text{ mEq/L}\\ \text{Anion gap (AG)} &= 35 \text{ mEq/L}\end{aligned}$$

Since the normal AG is 12 ± 2 mEq/L, this individual has utilized 23 mEq/L of HCO_3^- to buffer the ketoacids. If the production of ketoacids ceases and hepatic metabolism is restored through insulin administration, then 23 mEq/L of HCO_3^- could be added to body fluids. The new set of electrolytes would be:

$$\begin{aligned}[Na^+] &= 140 \text{ mEq/L}\\ [K^+] &= 5 \text{ mEq/L}\\ [Cl^-] &= 90 \text{ mEq/L}\\ [HCO_3^-] &= 38 \text{ mEq/L}\\ \text{Anion gap (AG)} &= 12 \text{ mEq/L}\end{aligned}$$

By assessing the value—(AG increment above 12 mEq/L) + (serum $[HCO_3^-]$)—and finding a value greater than 30, one can infer that some process has previously raised the bicarbonate content above normal even if the ambient total CO_2 level is subnormal at the current moment. Hence either metabolic alkalosis or respiratory acidosis is a component process of the acid–base disorder. Conversely, finding a value less than 20 suggests that the patient had a pre-existent metabolic acidosis or a respiratory alkalosis prior to the onset of the organic acidosis. Finally, the clinician may assess the alveolar–arteriolar O_2 gradient to determine the effectiveness of oxygenation as an initial assessment of respiratory gas exchange efficiency.

At this point the clinician is able to ascertain a tentative diagnosis and perform an arterial blood gas determination to conclude the process. Measurement of the blood gas will show whether the respiratory response to a metabolic disturbance (metabolic alkalosis or metabolic acidosis) or the metabolic (renal) response to a respiratory disturbance is as expected. The acid–base disorder could still be labeled a simple disturbance if the initial assessment of the clinical condition and the AG support that conclusion. Consulting the acid–base map (see Fig. 17-4) will provide the expected compensatory response to each disturbance. In the previously mentioned case of a patient with diabetic ketoacidosis and an initially increased (AG + total CO_2) concentration, the following arterial blood gases were obtained:

$$\begin{aligned}\text{pH} &= 7.18\\ P_{CO_2} &= 38 \text{ mm Hg}\\ [HCO_3^-] &= 15 \text{ mEq/L}\end{aligned}$$

In pure metabolic acidosis the ventilatory response to an $[HCO_3^-]$ lowered to 15 mEq/L would be a P_{CO_2} of 25 mm Hg (see Table 17-1 and Fig. 17-4). In this example, the patient shows a P_{CO_2} that is higher than the expected value of 25 for a patient with pure metabolic acidosis and a depressed HCO_3^- value of 15 mEq/L. Hence this patient demonstrates a so-called triple disturbance: a metabolic acidosis (low HCO_3^-, high AG), a metabolic alkalosis ($[HCO_3^- +$ AG increment above 12] >30 mEq/L), and a respiratory acidosis (P_{CO_2} higher than expected value given the lowering of

HCO_3^- level as determined from the acid–base nomogram or the formula for expected compensation). Therapy for this patient will require awareness of these various processes, since removal of one of multiple disturbances can induce a more severe expression of the still-present abnormality.

CHAPTER 18

Aging of the Respiratory System

Edward J. Campbell
Corrine R. Kliment

INTRODUCTION

The fastest growing segment of the U.S. population consists of individuals of age 65 and older. In the 2018 census, this segment comprised 52 million individuals or 16% of the population. Since the 1950s, the median age of the U.S. population has increased by 20 years.

The largest decrements in age-adjusted death rates have been occurring in older patients. With the increasing longevity of human population, it is necessary to understand the effects of aging on the respiratory system in healthy people. Perhaps, more importantly, because the age-related decrements in respiratory system function can be unmasked by disease, it is critically important to point out that the aged: (1) have an enhanced predisposition to lung disease; (2) have a decreasing reserve of respiratory system function that decreases their ability to cope with the stresses of illness, injury, and surgery; and (3) may have differing responses to therapy when compared with their younger counterparts.

Even in individuals who enjoy apparently good health, there are measurable decrements in function of the respiratory system with age. These changes occur progressively as a healthy individual grows older and are most marked beyond 60 years of age. Cross-sectional studies show clear differences between elderly and young persons with regard to the structure and function of the components of the respiratory system (Table 18-1). As we will see, however, caution must be exercised in ascribing observed changes to age alone. It is also necessary to be aware that longitudinal studies of "healthy" individuals followed to old age are essentially not available. Where appropriate, methodologic problems in the available cross-sectional studies are described.

Although age-associated changes can be measured easily by objective testing, it is important to note that the routine activities of healthy elderly persons are not limited by the decreasing respiratory system function. However, whereas youthful persons have a marked excess of functional capacity over the amount required to meet metabolic needs at rest or with stress (physiologic reserve), the respiratory system draws on this reserve as its function declines with age. Thus, the physiologic reserve, especially for alveolar gas exchange, is reduced with aging. This leaves elderly individuals vulnerable to stresses, diseases, and injuries that are weathered much more easily in the young.

ARE CHANGES IN THE RESPIRATORY SYSTEM CAUSED BY AGING OR RELATED TO AGE IN OTHER WAYS?

For decades, the phenomena explained purely by aging have been required to satisfy specific principles. Roughly according to Hayflick,[1] the changes must be: (1) intrinsic (as opposed to environmentally mediated); (2) universal; (3) progressive; and (4) usually detrimental to the organism. Developing an understanding of changes to the lung over time is complicated by the fact that the lung is an open system that is exposed to environment. As such, it is assaulted by respiratory infections and by a constant barrage of particulates and other air pollutants. In addition, the lungs are commonly exposed to tobacco smoke, to occupational dusts and fumes, and to effects of aspiration. At times, environmental influences are inextricably involved in the changes that are observed in the respiratory system over time. However, it is important to draw a distinction between alterations purely related to aging and those associated with older individuals. Purely age-related changes are biologic phenomena and irreversible. Other alterations associated with increasing age have the potential to be preventable, treatable, and/or reversible.

CHANGES IN THE UPPER AIRWAY

There is a clearly increased risk of aspiration in the elderly that is thought to be a consequence of a number of age-related factors, including comorbid illnesses and debility, medications, and the aging process itself. With regard to purely age-related changes, attention has been focused upon the cough and swallowing reflexes, both of which are protective against aspiration. In the past, these reflexes have been thought to be controlled primarily by the brainstem, but there is now evidence that cortical and subcortical structures play critical roles in their control.[2] By their nature, reflexive cough and swallowing activate both sensory and motor areas in the cortex. The sensory component, including the sensory cortex

TABLE 18-1 Respiratory System: Functional Divisions and Changes with Aging

Functional Division	Components	Function	Change(s) with Aging
Conducting airways	All airways not involved in gas exchange (mouth to terminal bronchioles)	Gas movement between environment and alveolar space	Slight changes in size; calcification; glandular hypertrophy
Lung parenchyma	Gas-exchanging airways and vessels; connective tissue framework	Gas exchange between alveolar space and capillary blood	Enlarged terminal airspaces; ventilation/perfusion mismatching
Bellows apparatus	Chest wall and muscles of respiration	Provide mechanical forces for ventilation	Increased rigidity of chest wall; decreased respiratory muscle strength
Ventilatory control	Respiratory control center (pons and medulla); carotid and aortic bodies	Maintaining homeostasis by altering ventilation to match metabolic needs	Markedly decreased responses to hypercapnia and hypoxemia
Cardiovascular system	Heart and systemic vasculature	Blood transport and tissue exchange of respiratory gases	Decreased maximal heart rate and cardiac output; decreased responsiveness to hypoxemia

in reflexive circuits, seems to be more vulnerable to aging than the motor component, including the motor cortex. Therefore, strategies to restore effective cough and swallowing reflexes should be focused upon compensations of sensory components.

Variable amounts of aspiration of both oropharyngeal contents (food particles, saliva, and oropharyngeal organisms), and also gastric contents (food particles and gastric secretions including gastric acid), are increasingly common with aging. Aspiration is particularly common in the very old. Because of the sensory alterations discussed earlier, aspiration in elderly individuals can be associated with few, or no, symptoms.[3]

A potentially important contributor to aspiration is gastroesophageal reflux. In accordance with the earlier discussion of sensory impairments, reflux esophagitis severity increases with age while heartburn severity decreases with age.[4] Consequences of gastroesophageal reflux may be exacerbated by esophageal motor abnormalities associated with aging. Recurrent aspiration of gastric contents in the elderly can lead to airway inflammation, bronchiectasis, and pneumonia.

STRUCTURAL CHANGES IN THE LUNG

Studies of the aging lung have shown changes in shape, with increase in anteroposterior diameter that leads to a "rounding" shape of the lung. These changes are presumably secondary to changes in the shape of the surrounding thoracic cage that are very common after the age of 75. In a study of 100 chest radiographs from individuals ranging in age from 75 to 93 years, 25% had severe kyphosis (>50 degrees) and 43% had moderate kyphosis (35–50 degrees) from vertebral fractures.[5]

■ Conducting Airways

The conducting airways consist of the air passages from mouth to the level of respiratory bronchioles. Their volume comprises the anatomic dead space, and their geometry is a primary determinant of airway resistance. The larger cartilaginous airways show a modest increase in size with age, resulting in slight but probably functionally insignificant increase in anatomic dead space. Although calcification of cartilage in the walls of the central airways and hypertrophy of bronchial mucus glands is seen in advanced age, these changes in the extraparenchymal conducting airways appear to have little or no physiologic significance.

Ciliary motility of both the upper and lower airways is important in normal lung clearance. Several studies have shown that ciliary function is significantly reduced with aging in the lung[6–8] and nasal tissue.[9] This reduction in ciliary function is often compounded by noxious stimuli such as cigarette smoke that reduce ciliary beat frequency. Dysfunctional ciliary beating likely further increases the risk of lower respiratory infections and inflammation in the elderly population.

■ Lung Parenchyma

After the age of 30 or 40, the respiratory bronchioles and alveolar ducts undergo progressive enlargement (Fig. 18-1). This change has been termed "ductectasia" because of the prominent finding of enlargement of alveolar ducts.[10] The proportion of the lung made up of alveolar ducts increases, and alveolar septa become shortened, leading to a "flattened" appearance of the alveoli. With the change in geometry, the distance between alveolar walls (known to morphologists as the mean linear intercept, or MLI) increases, while the surface-to-volume ratio of the lung decreases.[11] The age-related enlargement of the terminal respiratory units also produces a decrease in the percentage of parenchymal air contained within the alveoli.[12] The net result of these structural changes is that the alveolar surface area decreases by approximately 15% by age 70.

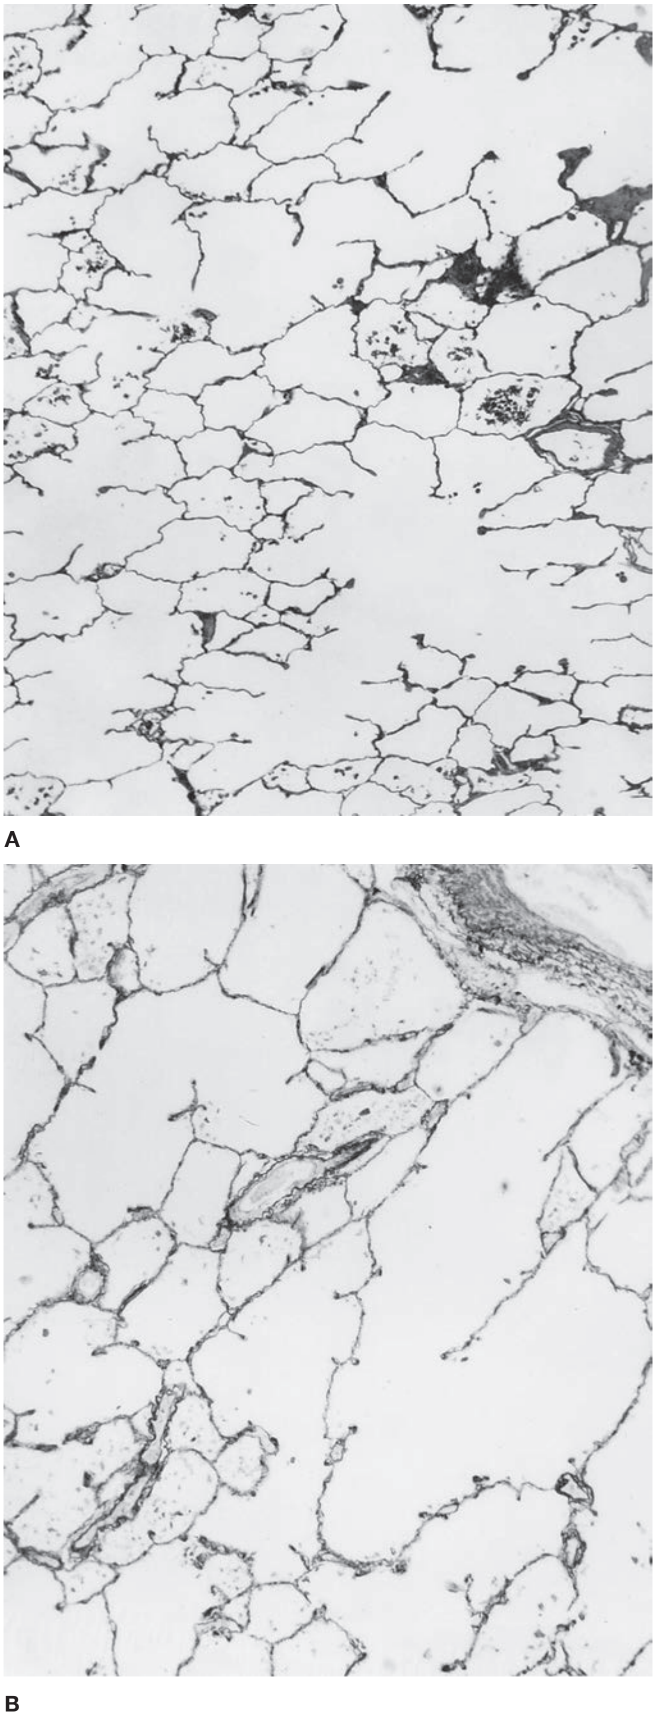

Figure 18-1 Histologic changes in the aging lung. **A.** Normal lung of a 36-year-old woman. **B.** Lung of a 93-year-old woman. In (**B**), the alveolar ducts are dilated, and shortening of inter-alveolar septa is observed. *(Reproduced with permission from Mayo Foundation; photomicrographs reproduced with permission from Charles Kuhn III, MD.)*

Pulmonary emphysema also is characterized by an increase in the size of terminal airspaces, an increase in MLI, and a decrease in surface area; however, destruction of alveolar septa with fusion of terminal airspaces is a defining characteristic of emphysema. There have been some reports of emphysematous lesions in aged lungs, but it is not certain that smokers were excluded from these studies. Since the fate of individual alveolar septa during the aging process has been somewhat controversial, some have referred to the histologic changes in aged lungs as "senile emphysema." A National Heart, Lung, and Blood Institute workshop on the definition of emphysema[13] weighed the available evidence and decided not to include age-related changes in the lung parenchyma under the definition of *emphysema*. To simplify terms and avoid confusion, they recommended use of the term *aging lung* to apply to the uniform airspace enlargement that develops with increasing age. Despite the continued use of "senile emphysema," this term should be avoided.

Computed tomography of the chest in individuals more than 75 years of age has shown a surprising prevalence (60%) of a subpleural basilar reticular pattern that was absent from images from a control population that was less than 55 years old. Lung cysts were seen in 25% of the elderly subjects, but none of the controls.[14] These findings are usually associated with interstitial lung disease, but in the elderly they seem not to reflect a clinically relevant disease process. Caution must be exercised to avoid overreacting to similar image findings in older patients.

CHANGES IN MECHANICAL PROPERTIES OF THE LUNGS

Both the lungs and chest wall are elastic. The resting volume of excised lungs is smaller than that contained within an intact thoracic cage, because the lungs are held at an increased volume by the outward recoil forces of the chest wall. Thus, in the intact thoracic cage, the lungs exert an inward recoil force. The retractile force of the lungs, or the "elastic recoil," can be measured during life by estimating the pleural pressure with an esophageal balloon at progressively decreasing lung volumes from total lung capacity to functional residual capacity (FRC), when the airways are open and there is no air flow. The negative pleural pressure is generated by the lungs' elastic recoil forces.

The pressure measurements may be displayed on a pressure–volume diagram (Fig. 18-2). Figure 18-2 compares, at the same volume, the elastic recoil pressures of a young man, a normal elderly adult, and a patient with emphysema. The normal elderly individual and the patient with emphysema both have a greater decrease in elastic recoil pressure than does a young person.[15] This is reflected in the leftward shift of their pressure–volume curves.[16–19] This loss of elastic recoil is the physiologic hallmark of emphysema. However, emphysema is characterized by a much greater loss of elastic recoil than is caused by aging alone.

There has been some disagreement regarding the effects of aging on lung compliance (Δ volume/Δ pressure; that is the slope of the pressure–volume relationship, Fig. 18-2). The question is whether there is a parallel leftward shift of the pressure–volume curve with aging (no change in compliance), or, instead, a steeper slope in addition to a shift (indicating an increase in compliance), as seen in emphysema. In aged individuals, the static pressure–volume curve is slightly steeper and is more concave in relation to the pressure axis. However, there is a general agreement that changes in lung compliance with aging are not physiologically significant.

Two forces in the lung parenchyma are responsible for producing the elastic recoil of the lungs. The greatest part of the elastic recoil forces is provided by the surface tension at the curved air–fluid interface of the small airways and alveoli. The second retractive force is that produced when the fibrous skeleton of the lung (primarily the elastic fibers) is stretched.

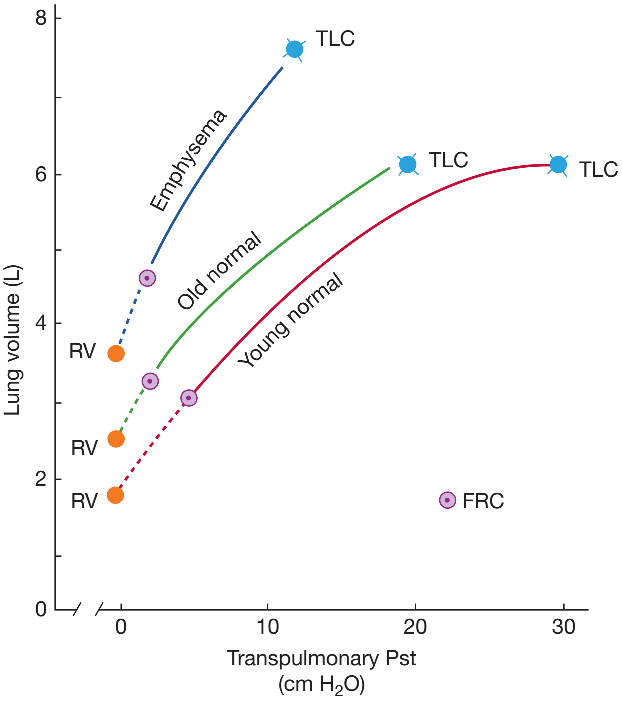

Figure 18-2 Static pressure–volume curves of the lungs. Static recoil pressure, expressed as transpulmonary pressure measured at various lung volumes, is plotted against lung volume on the ordinate. Note that at any lung volume, the recoil pressure is less in the aged individual than in the young, normal control, resulting in a pressure–volume curve that is shifted upward and to the left. For comparison, a curve for a patient with emphysema is shown. In emphysema, recoil pressures are reduced much more, and lung compliance (the slope of the pressure–volume relationship) is clearly abnormal. *(Reproduced with permission from Pride NB. Pulmonary distensibility in age and disease. Bull Physiopathol Respir. 1974;10(1):103–108.)*

■ Changes in Surface Forces

Most of the loss in lung recoil with age is likely to be related to the decrease in lung surface area. The loss of surface area that accompanies aging can be expected to reduce the area of gas–liquid interface, resulting in a decrease in the surface tension forces and, ultimately, a decrease in the total elastic recoil of the lung. Whether it is due to loss of air–liquid interface or to changes in lung structural macromolecules, the reduced elastic recoil has important consequences for the function of the intraparenchymal airways and, ultimately, on alveolar gas exchange and forced expiratory flow (see "Pulmonary Function Tests," below).

■ Changes in Structural Macromolecules

Weibel has produced elegant studies of the "integral fiber continuum" that extends from the hila to the pleura. This consists of axial fibers extending to the alveolar septae, and septal fibers extending to the pleura.[20] Although most proteins in the lung turn over relatively rapidly, the structural proteins, elastin and collagen, in the lung fibrous network provide a very stable, long-lived skeletal structure for the lung.

Elastic fibers consist in large part of an extremely hydrophobic, highly cross-linked, and very elastic macromolecule (elastin). These fibers are thought to contribute substantially to lung elasticity. Analysis of whole lungs has revealed that the elastin content actually increases (rather than decreases) with age. More recent evidence indicates that the increase in lung elastin with age is accounted for by an increase in pleural elastin; parenchymal elastin does not change.

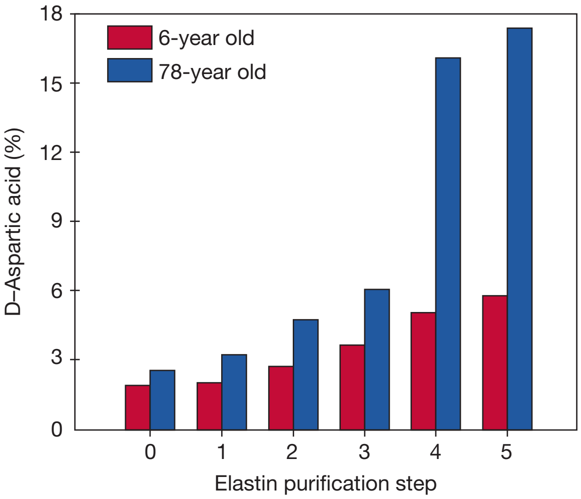

Figure 18-3 Longevity of human lung parenchymal elastin, as evidenced by in vivo racemization of aspartic acid. Each pair of bars shows results from two individuals with greatly differing ages at time of death. Step 0 of elastin purification represents whole lung parenchyma, while step 5 is purified elastin. D-aspartic acid detected in the 6-year-old specimen can be attributed to racemization that occurs during the analytical procedures, whereas, the difference in prevalence of D-aspartic acid between the young and old individual has resulted from racemization in vivo. Note that results from whole-lung hydrolysates (step 0) are similar for both specimens, reflecting their composition of proteins, having predominantly rapid turnover. However, purified elastin from the oldest specimen has racemized extensively in vivo, indicating that it was synthesized many decades before death. These data for elastin agree well with results for other very long–lived proteins. *(Reproduced with permission from Shapiro SD, Endicott SK, Province MA, et al. Marked longevity of human lung parenchymal elastic fibers deduced from prevalence of D-aspartate and nuclear weapons–related radiocarbon. J Clin Invest. 1991;87(5):1828–1834.)*

Careful studies of the elastic fibers in the lung parenchyma have shown that they are remarkably stable following postnatal lung growth. Certain biochemical changes in very long-lived proteins (change of amino acids into their mirror-image structures, or racemization) provide a type of "biological clock" that permits an estimate of the time that has elapsed since the proteins were synthesized. Because of the constraints of the protein synthetic mechanisms, only L-amino acids are incorporated into newly synthesized proteins. With the passage of years at body temperature, however, there is a readily measurable accumulation of D-aspartic acid. When all of the lung proteins are examined together, minimal D-aspartic acid is found. In purified lung elastin, however, there is an age-related accumulation of D-aspartic acid,[21] indicating that lung elastin is turning over very slowly if at all (Fig. 18-3). It has also been possible to estimate lung elastin turnover by measurement of the incorporation into elastic fibers of carbon 14 (^{14}C) from atmospheric nuclear weapons testing. For example, individuals who completed their postnatal lung growth prior to the nuclear age show no excess ^{14}C in their lung elastin, indicating absence of new elastin synthesis. In contrast, an appropriate excess of ^{14}C is found in the lung elastin of individuals whose lungs were growing in the post–weapons testing era. Modeling of the radiocarbon data indicates that the "mean carbon residence time" in elastin is 74 years.

Taken together, the amino acid racemization and radiocarbon data indicate that lung parenchymal elastin is stable over the human life span, and it appears that the elastin content of the lung parenchyma not only does not change with age, but the individual fibers persist for at least many decades.

Other studies of lung elastic fibers have shown changes in the location and orientation of individual fibers with age as well as changes in the cross-linking of elastin. Thus, some authors have suggested that remodeling of the lung architecture may occur without replacement of elastic fibers. In any case, at the present time, the age-related changes in connective tissue do not provide a sufficient explanation for the decrease in elastic recoil forces observed in the elderly.

Studies of collagen in alveolar walls of humans, as measured by hydroxyproline, have failed to show a consistent change in its quantity during aging.[22] Although human studies have not been done, studies in rodents and birds suggest that lung collagen fibers, like elastic fibers, are very long-lived.[23] Finally, although some qualitative changes in collagen during aging have been described (decreases in solubility and increases in intermolecular cross-links), these appear to have no relationship to changes in lung elastic recoil.

Although convincing evidence for very slow compensatory human lung growth (over many years) has been provided following pneumonectomy,[24] under more ordinary circumstances it appears that the lung adapts to changing dimensions of thorax by realignment of its fibrous skeleton rather than by molecular remodeling.

■ Changes in the Chest Wall

There is good evidence that the chest wall becomes more rigid with advancing age.[25] As may be seen in Fig. 18-4, the static pressure–volume curve of the chest wall is shifted to the right and is less steep

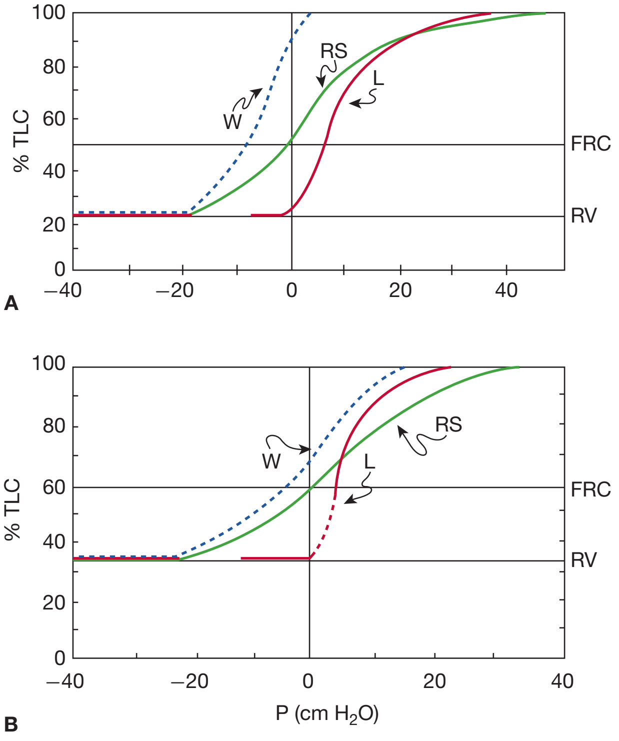

Figure 18-4 Static compliance relationships of the components of the respiratory system. (L, lungs; W, chest wall; RS, total respiratory system.) **A.** A 20-year-old man. **B.** A 60-year-old man. Note that the static compliance of the chest wall is substantially decreased (reduced slope) in the older individual, while functional residual capacity (the resting volume of the respiratory system, or the point at which the pressure gradient across the respiratory system is zero) increases. As in Fig. 18-2, it is also apparent that the static recoil pressure of the lungs is reduced in the older subject. *(Data from Mittman C, Edelman NH, Norris AH, et al. Relationship between chest wall and pulmonary compliance and age. J Appl Physiol. 1965;20:1211–1216; and Turner JM, Mead J, Wohl ME. Elasticity of human lungs in relation to age. J Appl Physiol. 1968;25:664–671.)*

with increasing age. The articulations of the ribs with the sternum and the spinal column may become calcified, and the compliance of the rib articulations decreases. The changes in rib articulations may be compounded by the development of kyphosis due to osteoporosis. The decreasing compliance of the chest wall demands greater work from the respiratory muscles. For example, in a 70-year-old person, approximately 70% of the total elastic work of breathing is expended on the chest wall, whereas this value is 40% in a 20-year-old person.

Figure 18-4 also demonstrates that the compliance of the total respiratory system decreases with age because the decrease in lung elastic recoil is outweighed by the changes in the mechanical properties of the chest wall.

CHANGES IN MUSCLES OF RESPIRATION

Age-related changes in non-respiratory skeletal muscle include decreased work capacity due to alterations in the efficiency of muscle energy, metabolism, atrophy of motor units, and electromyographic abnormalities. Based upon lessons learned with other skeletal muscles, it appeared likely that age-related abnormalities in respiratory muscles also would be found.

An early study by Black and Hyatt appeared to confirm age-related decrements in respiratory muscle function by measuring maximal inspiratory pressure ($P_{I_{max}}$) and maximal expiratory pressure ($P_{E_{max}}$) in 120 normal individuals (both smokers and nonsmokers) between the ages of 20 and 70.[26] Maximal respiratory pressures in females were 65% to 70% of those in males. No significant age-related changes were observed in individuals under the age of 55. Trends toward reduced maximal respiratory pressures with age were seen in both genders and with both $P_{I_{max}}$ and $P_{E_{max}}$. With the number of males studied, the change with age in $P_{I_{max}}$ was not statistically significant for male gender.

More recently, McElvaney and coworkers came to a different conclusion in a similar study of 104 healthy individuals over the age of 55.[27] They found a large variation in maximal respiratory pressures from individual to individual (as by Black and Hyatt), but no significant correlation with age. In contrast, in a third population of 160 healthy individuals who ranged in age from 16 to 75 years, Chen and Kuo found significant gender differences in maximal respiratory pressures as well as trends toward decrements with age for $P_{I_{max}}$ and $P_{E_{max}}$ in both genders. The age-related change in $P_{E_{max}}$ in males was not statistically significant with the sample size studied. When the 40 individuals of both genders in the youngest age group (16–30 years) were compared with the 40 individuals in the oldest group (61–75 years), the decrement in $P_{I_{max}}$ was 32% to 36%, while the decrement in $P_{E_{max}}$ was 13% to 23%.[28] Representative findings for maximal respiratory pressures in women are illustrated in Fig. 18-5.

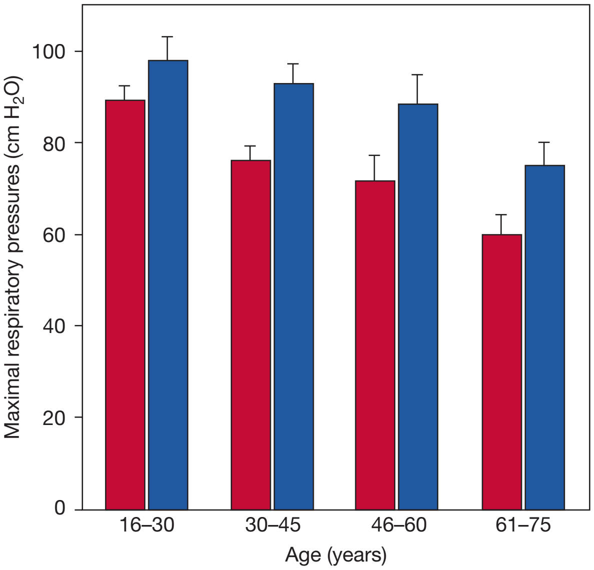

Figure 18-5 Representative variations in maximal respiratory pressures with age among women. Inspiratory and expiratory measurements were made at residual volume and total lung capacity, respectively. Maximal inspiratory pressure *(open bars)* and maximal expiratory pressure *(hatched bars)*. Error bars are standard errors of the mean. Although quantitatively moderate, variations with age were statistically significant for both measurements. *(Data from Chen H-S, Kuo C-S. Relationship between respiratory muscle function and age, sex, and other factors. J Appl Physiol. 1989;66(2):943–948.)*

Chen and Kuo also measured inspiratory muscle endurance against a resistive load and found significant decrements with age. Physically active men had greater inspiratory muscle endurance than sedentary men.

In summary, it appears that when populations of healthy individuals of widely differing ages are studied, moderate age-related decrements in respiratory muscle strength and endurance can be found. These studies usually define *healthy* only by the absence of disease and do not control for physical activity. They are complicated by marked interindividual variability, and longitudinal studies have not been reported. Continuous respiratory muscle activity may have a training effect that leads to better preservation of respiratory muscle function when compared with other skeletal muscles. Finally, physical activity may have an additional training effect that enhances inspiratory muscle endurance in all age groups.

CONTROL OF BREATHING

In young individuals, minute ventilation is matched with metabolic demands. As a result, arterial blood gas values remain stable throughout a wide range of activities from rest to strenuous exertion, while oxygen consumption and carbon dioxide production are varying widely. Similarly, when the efficiency of gas exchange is diminished by lung disease or congestive heart failure, appropriate increases in minute ventilation minimize the resulting hypercapnia and/or hypoxemia in healthy young individuals. The ventilatory control system is described in detail in Chapter 11.

Ventilatory control mechanisms are typically tested by stressing the respiratory system, by inducing either hypoxemia or hypercapnia while monitoring ventilatory parameters (and often cardiac parameters as well). Such tests have shown striking differences between young and elderly individuals in both ventilatory and cardiac responses.

■ Diminished Ventilatory Response to Hypercapnia

Kronenberg and Drage compared the ventilatory responses to hypercapnia in eight young (mean age, 25.6 years) and eight elderly (mean age, 69.6 years) individuals.[29] During the tests, the subjects were asked to rebreathe 5% CO_2, while their $P_{A_{O_2}}$ was held above 200 mm Hg by supplemental oxygen to eliminate hypoxic ventilatory drive. Measurements were made while $P_{A_{CO_2}}$ was allowed to rise to 65 mm Hg. Although there was considerable individual variation and some overlap between the groups, the elderly individuals had a significantly diminished ventilatory response to hypercapnia, measured as the slope of the relationship between ventilation and $P_{A_{CO_2}}$.

■ Diminished Ventilatory Response to Hypoxia

When Kronenberg and Drage measured the ventilatory response to hypoxia at constant CO_2, they found even more striking differences between the young and elderly subjects (Fig. 18-6). For example, the ventilatory response to a $P_{A_{O_2}}$ of 40 mm Hg was uniformly smaller in the older subjects, and there was no overlapping between the groups.[29] The mean minute ventilation at a $P_{A_{O_2}}$ of 40 mm Hg was 40.1 and 10.2 L/min in the young and old groups, respectively.

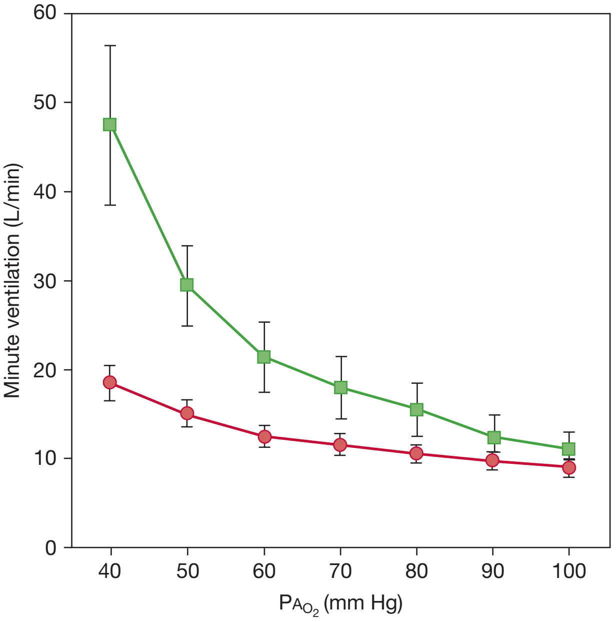

Figure 18-6 Variations with age in ventilatory responses to hypoxia. Eight normal men aged 64 to 73 *(circles)* and eight controls aged 22 to 30 *(squares)* were subjected to isocapnic progressive hypoxia by a rebreathing method. Data values are means, with standard errors of the mean shown by the error bars. Note that the ventilatory responses differ strikingly between the elderly individuals and the controls. *(Reproduced with permission from Kronenberg RS, Drage CW. Attenuation of the ventilatory and heart rate responses to hypoxia and hypercapnia with aging in normal men. J Clin Invest. 1973;52(8):1812–1819.)*

Diminished Occlusion Pressure Responses

Peterson et al. confirmed the previously discussed observations and have shown that the differences in responses of elderly subjects to both hypercapnia and hypoxia are due to a lesser increase in tidal volume while the ventilatory rate increases normally. Since this observation could be caused by differences in respiratory muscle strength or increases in chest wall stiffness, the authors also measured airway occlusion pressures, which are valuable indices of respiratory drive that are not affected by respiratory muscle strength or respiratory mechanics.[30] The measurement (P_{100}) is the negative pressure at the mouth, measured 100 ms after the start of inspiration against an occluded airway. The occlusion pressure responses to both hypoxia and hypercapnia (Fig. 18-7) were significantly reduced in the 10 elderly subjects studied by Peterson (mean age, 73.3 years) when compared with nine young control subjects (mean age, 24.4 years). Although the elderly individuals had reduced respiratory muscle strength (mean, 24% lower maximal static inspiratory pressure), the differences in occlusion pressure persisted when normalized for these differences.

The previously mentioned seminal studies of ventilatory control have been discussed in some detail out of respect for their groundbreaking conceptual importance. Subsequent studies have created some confusion that appears likely to be due to methodologic differences, ages of subjects, and small sample sizes. However, in 14 of 16 studies reviewed by Lalley, ventilatory responses in the elderly were found to be abnormal.[31]

In summary, the reduced responsiveness in tidal volume to either hypoxemia or hypercapnia with age is apparently due to a reduced responsiveness of ventilatory drive or neural output from the respiratory center. It has not been determined whether the diminished ventilatory drive results from altered chemoreceptor function or from altered function of the respiratory center. Kronenberg and Drage favored altered receptor function based on their observation that elderly subjects responded to an alveolar oxygen tension of 40 torr with only an 11% increase in heart rate, whereas the young subjects responded with a 34% increase.

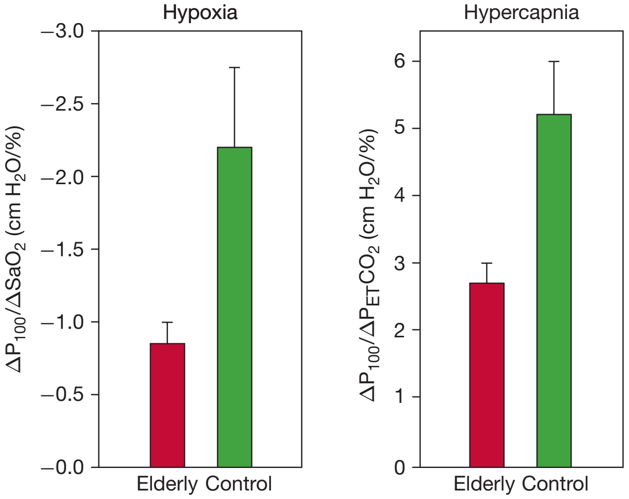

Figure 18-7 Variations with age in occlusion pressure responses to hypoxia and hypercapnia. Data shown are slopes of relationships between occlusion pressure responses and either Sa_{O_2} or end-tidal P_{CO_2}; error bars are standard errors of the mean. Elderly individuals had significantly diminished occlusion pressures in response to both hypoxia and hypercapnia. Both differences were significant, with $p < 0.01$. *(Reproduced with permission from Peterson DD, Pack AI, Silage DA, et al. Effects of aging on the ventilatory and occlusion pressure responses to hypoxia and hypercapnia. Am Rev Respir Dis. 1981;124(4):387–391.)*

Respiratory Load Compensation and Dyspnea

Reflex compensation is a response that maintains constant ventilation during a change in respiratory mechanical load, as occurs in lung disease, changes in posture, and mouth versus nose breathing. Akiyama et al. measured responses to inspiratory flow-resistive loading in young and elderly individuals and found significant differences.[32] In the young control group, inspiratory loading resulted in an increase in P_{100} at each level of induced hypercapnia, such that inspiratory loading did not change the ventilatory response to hypercapnia when compared with unloaded responses. In marked contrast, the P_{100} in the elderly group did not change when an inspiratory load was applied. In the absence of a compensatory change in ventilatory drive, ventilatory responses to hypercapnia were reduced during inspiratory loading in the elderly group.

At each level of P_{CO_2}, the intensity of perceived dyspnea in response to inspiratory loading was greater in the elderly than in the control group. Thus, the sensation of dyspnea was intact or enhanced in the elderly subjects, while their compensatory responses were reduced. This suggests the possibility that elderly individuals may complain of a greater dyspnea than younger individuals with similar pathophysiologic deterioration.

Sensitivity to Respiratory Depression by Opioids and Sedatives

Older individuals are substantially more sensitive to respiratory depression by opioids and sedatives. This phenomenon demands extra vigilance when these medications are prescribed in non-intubated elderly patients. The enhanced drug effect has been shown to be multifactorial, and the various mechanisms involved are beyond the scope of this chapter.[33–35] However, the dangers associated with higher levels and more prolonged effects of these drugs are real and potentially catastrophic.

PULMONARY CIRCULATION

Invasive physiologic studies of pulmonary artery catheterization have typically been biased by including only subsets of patients whose signs and symptoms led to referral for heart catheterization and who, therefore, may not be representative of a "healthy" cohort. Further, age-related changes in the pulmonary circulation are difficult or impossible to separate from changes due to heart disease or age-related changes in cardiac function.

Ehrsam et al. reported a retrospective analysis of right heart catheterization studies performed in 125 asymptomatic subjects who ranged from 14 to 68 years of age.[36] Small increases in right atrial, pulmonary artery, and pulmonary artery wedge pressures observed in the highest age group disappeared when values were adjusted for sex, weight, and height. No significant age-related changes were found in cardiac output, stroke volume, or oxygen uptake. Age explained 10% or less of the total variation in the hemodynamic and pressure variables when assessed by multiple regressions. During supine exercise with a bicycle ergometer, however, pulmonary artery and wedge pressures increased with age, particularly in subjects over the age of 45. The changes were highly significant with age accounting for 12% to 30% of the total variation when assessed by multiple regressions. Finally, pulmonary artery resistance showed a highly significant increase with age, whether measured at rest or during exercise, with age contributing 12% to 27% to the total variation in pulmonary artery resistance. Although the cohort studied were all asymptomatic and ambulatory, it is possible that silent coronary artery disease was present in some of the subjects, and the prevalence of coronary artery disease can be expected to increase with age. Moreover, younger patients tended to be referred for evaluation of a heart murmur, whereas the older patients were referred for "pulmonary investigation" that included coin lesions, hilar lymphadenopathy, "previous pulmonary infiltrates," and smoke inhalation. Cigarette smoking history was not discussed. Thus, it is not certain that the younger and older patients were strictly comparable.

Davidson and Fee reported the results of right-heart catheterization at rest in 47 normal subjects (smokers were included) who were free of coronary disease and had normal left ventricular systolic function.[37] The investigators found highly significant but quantitatively modest age-related increases in mean pulmonary artery pressure, pulmonary vascular resistance, and pulmonary/systemic vascular resistance ratio, but they found no age-related differences in pulmonary artery wedge pressure. The authors felt that the most likely explanation for the age-related changes in pulmonary artery pressure and pulmonary vascular resistance was a primary abnormality of the pulmonary vascular bed, but they could not exclude the effects of subtle abnormalities in left ventricular function.

In summary, studies of pulmonary hemodynamics with aging are limited by retrospective design, bias in patient selection, and potential effects of smoking. Minor increases in pulmonary vascular resistance and age-related increases in pulmonary artery wedge pressure during exercise have been reported. These age-related changes may not be physiologically significant.

PULMONARY FUNCTION TESTS

Lung function and exercise capacity decline with age in concert with numerous other physiologic, morphologic, and biochemical changes. Descriptions of "normal" age-related changes are confounded by an increasing prevalence of disease, chronic illness, medication use, and an increasingly sedentary lifestyle. Further, chronologic age only approximates physiologic age; the two often differ significantly. Chronologic age is, therefore, an imperfect measure for indexing changes with senescence. While it would be desirable to isolate the effects of biologic aging (aging in the absence of disease), it is essentially impossible to do so. The best studies to do so are longitudinal, tracing change with time, because they avoid the obvious biases of cross-sectional studies. Longitudinal studies, however, have methodologic problems and biases of their own, the most obvious being that the healthy elderly represent a healthy survival population. If, as a group, they have better than average lung function, they would not represent the general population of elderly people well.

■ Lung Volumes

Figure 18-8 illustrates typical lung volume changes with aging based on cross-sectional studies. With the exception of vital capacity, the effect of aging on lung volumes is based on cross-sectional rather than longitudinal data because there are almost no longitudinal studies of static lung volumes. Total lung capacity (TLC), the volume of air in the lungs at the end of a maximal inspiration, is marked by the point at which the recoil pressure exerted by the respiratory system is exactly counterbalanced by the maximal inspiratory pressure generated by the respiratory muscles. Since both the compliance of respiratory system (lung and chest wall combined) and maximum inspiratory pressure fall with aging, TLC might also be expected to fall. However, in seven cross-sectional studies of TLC summarized by the European Coal and Steel Community, four of the studies in men and three of those in women did not find a significant age coefficient.[38] The remaining studies found only small declines in TLC with age, on the order of −8 to −19 mL/year. When these study results were combined into average equations, no significant age coefficients were reported for either men or women. McClaran et al. measured lung volumes twice in 18 healthy, fit men.[39] The first measurement was at a mean age of 67 and the second was 6 years later. Although average TLC fell 25 mL/year, the change was not statistically significant. The study was small and the interval was short.

In summary, current cross-sectional studies suggest that TLC either does not decline with age or declines very slowly. It is interesting to speculate on the possibility that cross-sectional studies of TLC might be confounded because they typically index TLC to both age and height. Height declines with aging, and maximum height during a life span appears to increase with successive generations. The

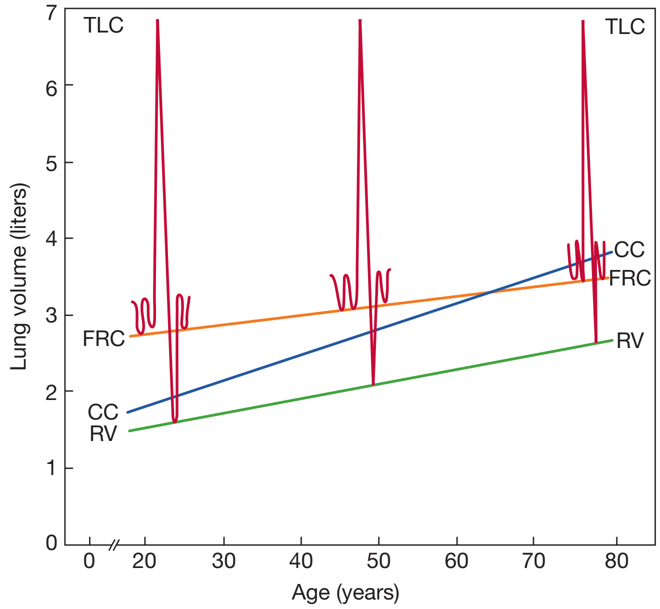

Figure 18-8 Schematic illustration of lung volume changes with age based on cross-sectional studies in seated individuals. (CC, closing capacity; FRC, functional residual capacity; RV, residual volume.) Although not labeled, vital capacity (VC) is TLC, total lung capacity; TLC minus RV. The most consistent changes are an increase in RV and a decrease in VC. *(Reproduced with permission from Fishman AP: Pulmonary Diseases and Disorders. New York, NY: McGraw Hill; 1992.)*

authors believe that longitudinal studies of TLC with age are likely to show small but significant declines with age.

Both slow and forced vital capacity (FVC) decline with age, more rapidly in men than in women. Average decrements in vital capacity per year vary considerably; in cross-sectional studies, declines range from 21 to 33 mL/year in men and 18 to 29 mL/year in women. Theoretically, longitudinal studies should provide better estimates of the effect of aging on lung function. Ware et al., in a study containing both longitudinal and cross-sectional computations, found cross-sectional falls in FVC for men and women to be −34 and −27.8 mL/year, respectively.[40] The longitudinal estimates were −40 mL and −31.3 mL/year, respectively. This study contradicts the generally held concept that longitudinal studies show smaller declines in FVC than cross-sectional studies. Currently, it is not certain whether longitudinal studies are all that much different from cross-sectional studies in describing declines in FVC and forced expiratory volume in 1 s (FEV$_1$). Longitudinal studies tend to show an acceleration in the rate of loss in FVC and FEV$_1$ as age advances.

Cross-sectional studies of residual volume (RV) and the RV/TLC ratio consistently show increases with age. In the young, RV, the volume of air in the lungs at the end of a maximal expiration, is the volume at which the outward static recoil pressure of the respiratory system is counterbalanced by the maximal pressure exerted by the expiratory muscles. In older subjects, expiratory flow never completely reaches zero and the determination of RV is made partly by the length of time an individual can maintain expiratory effort.[41] Other factors leading to an increased RV with aging include loss of lung recoil, decreased chest wall compliance, decreased expiratory muscle force, and increased small airway closure (air trapping) in dependent lung zones. Time of exhalation and increase in air trapping are probably more important than changes in lung and chest wall compliance in explaining the increase in RV with aging.

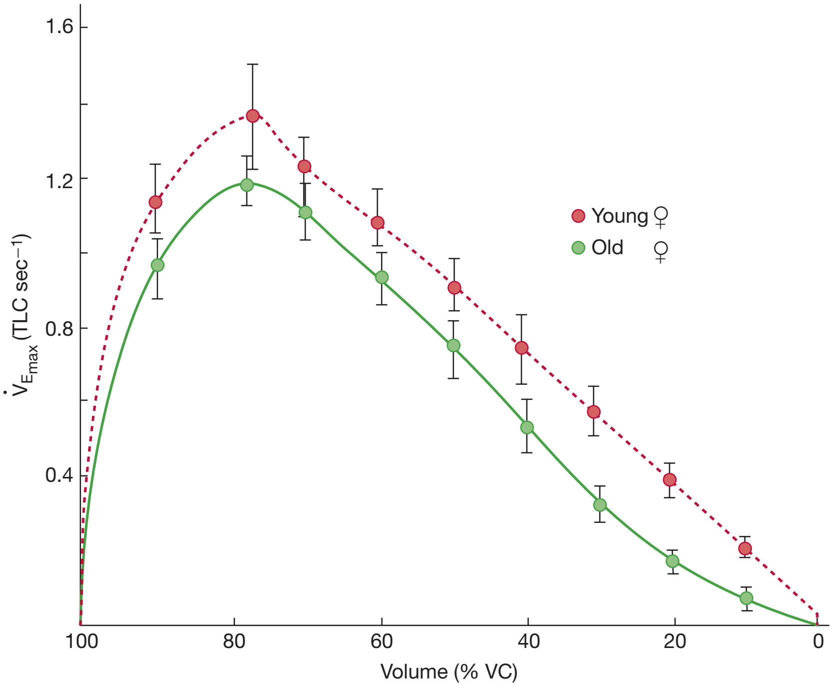

Figure 18-9 Illustrative maximal flow–volume curves for healthy “elderly” women (mean age, 63 years) and healthy young women (mean age, 25 years). Although all flows tend to be reduced with aging, the reduction in flow is most evident at lower lung volumes, where the flow–volume curve is clearly concave to the volume axis. *(Reproduced with permission from Fishman AP: Pulmonary Diseases and Disorders. New York, NY: McGraw Hill; 1992.)*

FRC is also determined by the balance of the elastic recoil forces of the lung and chest wall—but, in this instance, the equilibrium occurs at the end of a quiet (unforced) exhalation. Since lung recoil falls and the chest wall stiffens with age, one would expect FRC to increase. Cross-sectional studies, however, show inconsistent results, with most showing no change in FRC with aging. Studies that find an increase in FRC with aging show a small positive age coefficient on the order of 7 to 16 mL/year. McClaran’s longitudinal study found FRC to increase 40 mL/year, but again, the change was not significant.[39] Despite the conflicting data, it is generally believed that FRC increases with aging.

Loss of lung recoil also changes the volume at which airway closure occurs. When adults exhale fully, small airways close in the region of the terminal bronchioles in dependent lung zones. The lung volume at which this closure begins is measured as closing volume or, if it is added to RV, closing capacity. Closing volume increases linearly with age from about 5% to 10% of TLC at age 20 to about 30% of TLC at age 70.[16] The loss of lung elastic recoil, a possible decrease in the recoil of the intra-pulmonic airways, and decreases in small airway diameter probably explain most of the changes in CV.

Closing volume encroaches on tidal volume by about age 44 when subjects are supine and about age 65 when they are seated (Fig. 18-8). Airway closure during tidal breathing explains most of the decrease in arterial oxygen tension ($P_{A_{O_2}}$) observed with aging[42,43] and may contribute to an aging-related increased frequency dependence of compliance.

■ Airflow

While essentially all expiratory flows measured during a maximum expiratory maneuver decrease with age, the declines are most evident at lower lung volumes (Fig. 18–9). Nunn and Gregg, in a study of 225 male and 228 healthy female nonsmokers,[44] reported a modest, nonlinear decrease in peak expiratory flow (PEF) with aging (Fig. 18-10), which reached a high point at age 30 to 35; a decline became evident at about age 45. After age 50, the average decline was about 4 L/min per year in men, about 2.5 L/min per year in women.

Figure 18-11, from Paoletti et al., illustrates changes in FEV$_1$ during growth, maturation, and senescence.[45] Changes in FVC are similar. In one model of aging, FVC and FEV$_1$ increase progressively during the growth phase until about age 12. In the maturation phase (during adolescence), there is an acceleration of these increases. Increases in FVC and FEV$_1$ are seen up to about 20 years in women and about 25 years in men; increases in lung volumes occur even after somatic growth ceases. There appears to be a plateau phase where there is little or no change in FVC or FEV$_1$ prior to the onset of a decline. However, Robbins et al. demonstrated that, while the plateau correctly represents average data, lung function is often increasing or decreasing in individuals (Fig. 18-12). Their study confirms the suspicion that the “plateau” phase represents the merging of slower maturation-related increases in FVC and FEV$_1$ in some subjects, with subtle decreases in others.[46] In the decline phase, there appears to be acceleration in the rate of loss of FVC and FEV$_1$ as age progresses. An accelerated rate loss at older ages is, however, not found in all studies. The rate of decline in FVC and FEV$_1$ with age tends to be greater: (1) in men; (2) in taller individuals; (3) in

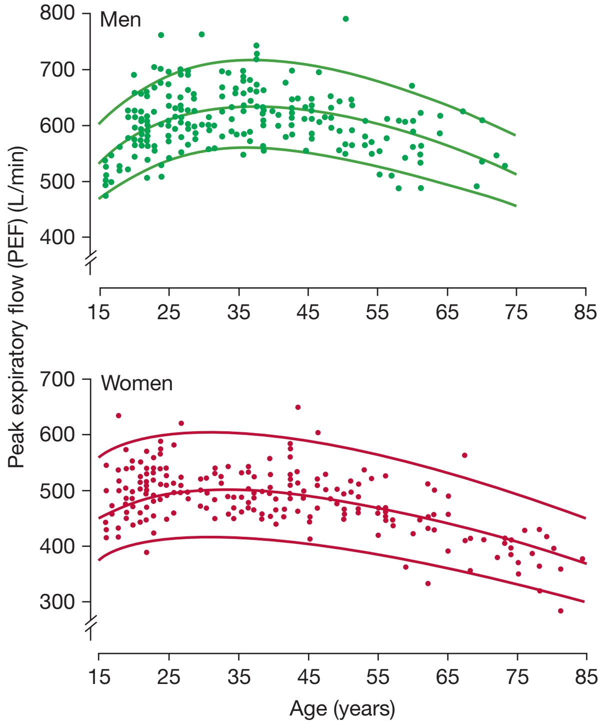

Figure 18-10 Changes in peak expiratory flow in 225 males and 228 females who were healthy nonsmokers. The *center line* is a regression curve representing mean data and the boundaries are 90% confidence intervals. *(Reproduced with permission from Nunn AJ, Gregg I. New regression equations for predicting peak expiratory flow in adults. Br Med J. 1989;298(6680):1068–1070.)*

individuals with larger baseline values; and (4) in individuals with increased airway reactivity.

■ Airways Resistance

Total airway resistance measured at FRC does not change with aging. Since upper airways increase and smaller airways decrease in size with aging, it is likely that peripheral airway resistance increases and central airway resistance decreases. That total airway resistance does not change with aging may be a function of the counterbalancing of these two opposite changes. However, since about 90% of total airway resistance resides in the upper airways, significant changes in peripheral airway resistance might not be readily reflected in total airway resistance. Significant increases in peripheral airway resistance with age also would be consistent with the more dramatic decreases in maximum flow observed at low lung volumes.

■ Gas Exchange

The carbon monoxide diffusing capacity (DL$_{\text{CO}}$), also known as transfer factor (TL$_{\text{CO}}$), declines with age. Earlier cross-sectional studies report a linear decline in DL$_{\text{CO}}$ of about −0.2 mL CO/min per mm Hg per year for men and −0.15 mL CO/min per mm Hg per year for women. These declines are roughly 0.5% per year. In a large representative sample of U.S. adult men, Neas and Schwartz found an almost linear fall in DL$_{\text{CO}}$.[47] In women, however, they found a nonlinear, quadratic decline in DL$_{\text{CO}}$ with age. After age 47, the nonlinear component was not significant and the decline in DL$_{\text{CO}}$ was identical to that in the earlier studies. The decline in DL$_{\text{CO}}$ with age did not vary with race.

The decline in DL$_{\text{CO}}$ with age is not explained by increased inhomogeneity of gas distribution. Measured DL$_{\text{CO}}$ falls as alveolar P_{O_2} increases, and venous hemoglobin concentration falls. Neither alveolar P_{O_2} nor hemoglobin concentration varies enough with age to explain the aging decline in DL$_{\text{CO}}$. The magnitude of the decline in DL$_{\text{CO}}$ corresponds fairly well to the magnitude of the known aging-related decrease in the internal surface area of the lung.

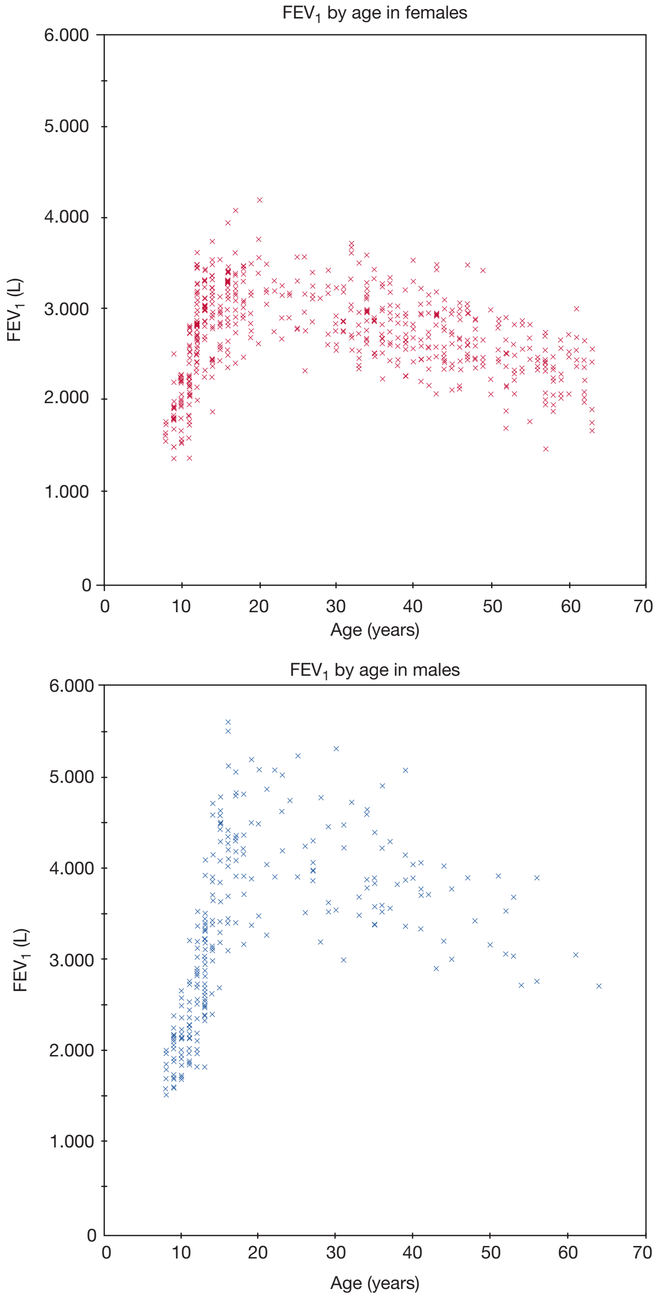

Figure 18-11 Change in FEV$_1$ with age from a cross-sectional study of 538 females and 263 males selected as "normal" from a larger study of 3289 subjects. Changes in FVC are similar. *(Reproduced with permission from Paoletti P, Pistelli G, Fazzi P, et al. Reference values for vital capacity and flow-volume curves from a general population study. Bull Eur Physiopathol Respir. 1986;22(5):451–459.)*

The components of DL$_{\text{CO}}$ are membrane diffusing capacity (Dm) and pulmonary capillary blood volume (Vc). Both Dm and Vc decrease with age. In a cross-sectional reference value study of 54 male and 36 female healthy nonsmokers, the decline in Dm and Vc with age were found to be linear.[48] Membrane diffusing capacity fell at about 0.6% per year in both men and women. Pulmonary capillary blood volume fell at about 0.3% per year.

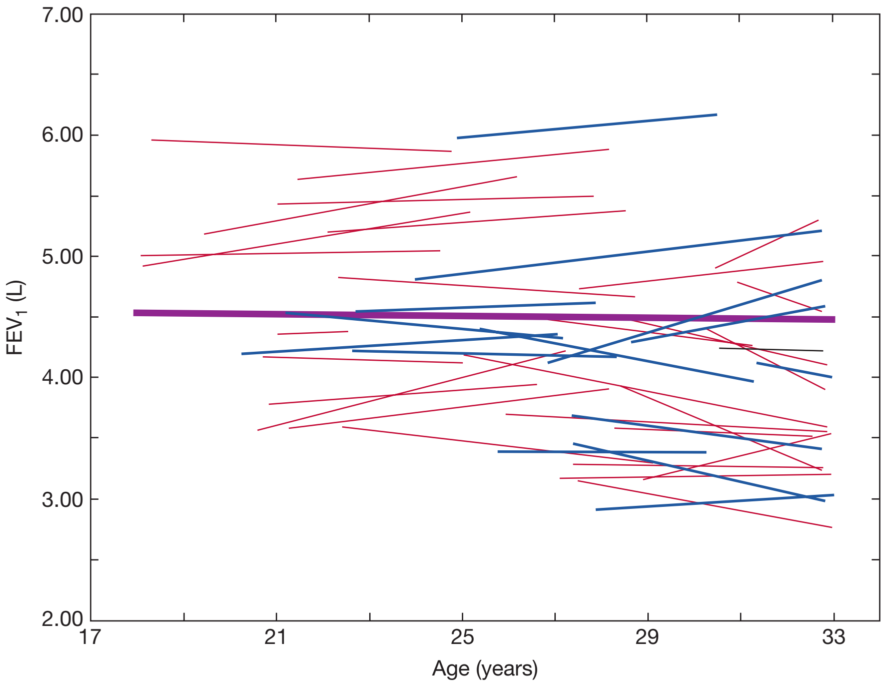

Figure 18-12 Predicted FEV_1 trajectories from 44 men based on linear regressions of longitudinal data. Nonsmokers *(fine lines)* and smokers *(dashed lines)*. The heavy line is based on the entire group's data. While the group's data show no change with age, data for individuals show both increases and declines with age during this time period, when a plateau in lung function was theorized to occur. *(Reproduced with permission from Robbins DR, Enright PL, Sherrill DL. Lung function development in young adults: Is there a plateau phase? Eur Respir J. 1995;8(5):768–772.)*

Although alveolar oxygen pressure (PA_{O_2}) remains constant with age, arterial P_{O_2} (Pa_{O_2}) decreases and the alveolar–arterial oxygen tension gradient ($PA - Pa_{O_2}$) increases with aging (Fig. 18-13).[49] The decline in Pa_{O_2} with aging is more pronounced when subjects are studied in a recumbent as contrasted with an upright position. The most likely explanation for the decline in Pa_{O_2} with aging is increased mismatching of ventilation to blood flow ($\dot{V}E/\dot{Q}$) as airway closure begins to occur during tidal breathing. Increased ($\dot{V}E/\dot{Q}$) mismatching with aging is also associated with an increase in physiologic dead space.[50,51] Hypoventilation does not contribute to the age-related fall in Pa_{O_2}, since Pa_{CO_2} and pH do not change with age (Fig. 18-13).

EXERCISE CAPACITY

Peak $\dot{V}_{O_2}$ ($\dot{V}_{O_2\,peak}$) and maximum work capacity decrease with aging in both sedentary and active individuals.[52] $\dot{V}_{O_2\,peak}$ (L/min) increases until about age 20. Declines are evident at about age 25 in both men and women and continue at about 1% per year (Fig. 18-14). If one expresses $\dot{V}_{O_2\,peak}$ as a function of body weight (L/kg per min), the decline is evident much earlier, perhaps in the first decade of life. The magnitude of the decline in $\dot{V}_{O_2\,peak}$ tends to be greater in longitudinal than in cross-sectional studies and occurs roughly twice as fast in sedentary than in physically active persons. Most, but not all, studies report linear declines in $\dot{V}_{O_2\,peak}$ with age, even though a nonlinear decline would be expected based on the number and type of variables that affect exercise capacity.

The decline in exercise capacity with age occurs as a result of normal aging but is accelerated by lifestyle issues. Aging is associated with significant changes in body configuration. Specifically, there is an increase in total body weight, primarily representing an increase in fat mass, since fat-free mass (mostly muscle mass) decreases with aging. The changes are most pronounced in sedentary persons. Muscle mass decreases, with a preferential atrophy of type II muscle fibers, and is associated with a decrease in muscle capillarization and oxidative activity. Muscle strength decreases on the order of 2%/year from ages 20 to 70. Variables associated with loss of exercise capacity with aging are listed in Table 18-2.

While exercise capacity declines with aging, it is also clear that the ability to respond to exercise conditioning is well maintained even at very advanced ages. Elderly individuals respond to both endurance and resistive training with improvements similar in magnitude

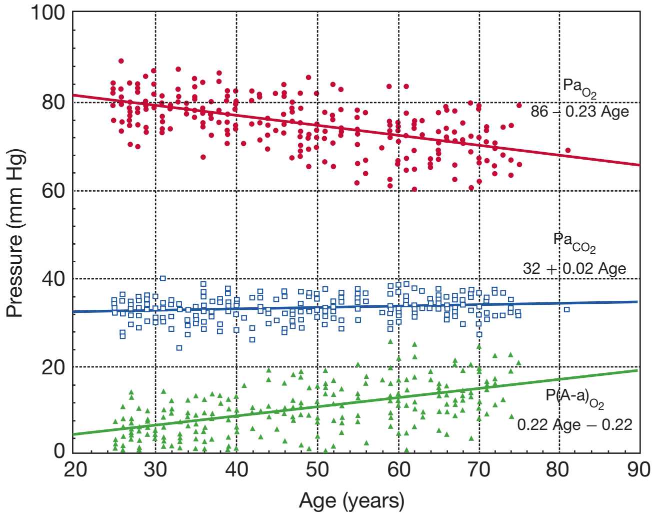

Figure 18-13 Change in Pa_{O_2}, Pa_{CO_2} and A-a gradient $P(A-a)_{O_2}$ with age. Data were obtained from 200 healthy men and women living in Salt Lake City, UT (altitude = 1400 m). Sea-level data would be similar, with a small upward shift in Pa_{O_2} and Pa_{CO_2}.

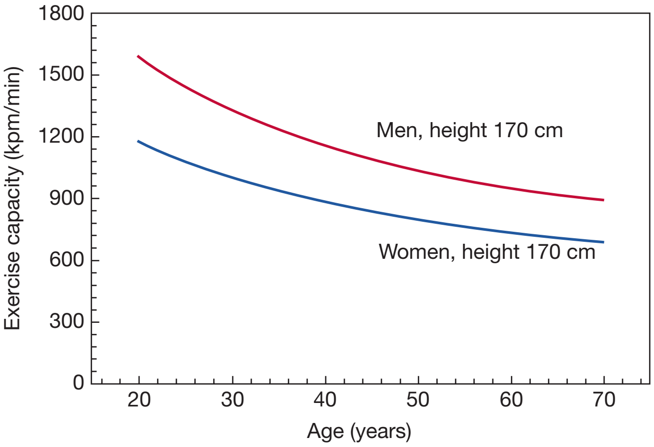

Figure 18-14 Decline in maximum exercise capacity with age. Exercise capacity declines nonlinearly with age. Maximum work capacity correlates strongly with peak oxygen uptake. *(Reproduced with permission from Jones NL, Summers E, Killian KG. Influence of age and stature on exercise capacity during incremental cycle ergometry in men and women. Am Rev Respir Dis. 1989;140(5):1373–1380.)*

TABLE 18-2 Variables Associated with a Decline in Exercise Capacity with Age

Variable	Comment
Decreased muscle mass	These changes especially affect $\dot{V}_{O_2}$ calculated per kg of body weight
Increased fat mass	
Decreased tissue oxygen delivery	As a result of the decreased cardiac output and maximal $C(a-\bar{v})_{O_2}$, delivery and extraction are reduced; decreased cardiac output is a major contributor to the age–related decline in exercise capacity
Decreased maximal heart rate	
Decreased stroke volume	
Decreased maximal $C(a-\bar{v})_{O_2}$ difference	
Maximum voluntary ventilation	
Increased ventilation at each workload	At each workload, older individuals breathe more and work harder for each breath than younger persons; however, the effect is small and contributes little to the decline in exercise capacity with aging
Increased oxygen cost of breathing	
Sedentary lifestyle	Lifestyle issues play a large role in the rate at which exercise capacity is lost with age; the good news is that, like other deconditioned groups, the elderly respond very well to exercise training
Decreased training intensity in active persons	
Decreased willingness to work to maximal level during tests	

to those seen in the young.[52–54] There are equivalent increases in $\dot{V}_{O_{2\,peak}}$, muscle mass, capillarization of muscle tissue, muscle oxidative activity, and general muscle strength.

LUNG PARENCHYMAL AND AIRWAY INFLAMMATION

Chronic low-level inflammation has been linked to aging of tissues, including in the lung.[55] In recent years, there has been considerable interest in the presence and control of lung inflammation in elderly individuals, and this has become a confusing subject. A variety of quantitative abnormalities in mediators of inflammation have been described in elderly individuals that have mostly been in the direction of increased lung parenchymal and airway inflammation. However, these differences from younger subjects must be viewed in the context that elderly individuals have impaired cough, increased evidence of gastroesophageal reflux, and decreased effectiveness of the ciliary escalator. All of these abnormalities can be expected to lead to an increased load of particulates and microorganisms in the lower respiratory tract, and/or recurrent episodes of aspiration. As a striking example of studies of airway inflammation, the mean quantity and percentage of neutrophils in broncho-alveolar lavage fluid have been found to be increased in elderly individuals, but many of the studied elderly subjects were indistinguishable from young normal subjects.[56] The increased mean values in the elderly were strongly influenced by outlying high values in a subpopulation, and thus presumably did not result from a direct effect of aging.

Significant changes to immune cell function occur with aging. The innate immune system, such as neutrophils, macrophages, and dendritic cells, is the rapid, initial line of defense against invading pathogens, while the adaptive immune system (T- and B-cells) is a slower-onset response designed for specificity and long-term responses. Intrinsic cellular dysfunction occurs with both arms of the immune system. Immunosenescence describes the decline in immune cell function, reduced pathogen recognition, signaling, and clearance. For example, neutrophils and macrophages have impaired migration to sites of injury, phagocytic function, and bacterial killing function in both aging patients and those with COPD.[57] In elderly individuals, B-cells have reduced antibody responses to influenza vaccination.[58] A second process termed *inflammaging* describes an increase in chronic inflammatory cells in tissues that occurs with aging, albeit with ineffective function of these cells. These age-related changes and dysfunction of the immune system likely have important impacts on lung function, chronic disease development, and treatment responses.

SLEEP

Sleep complaints from elderly patients present a difficult problem for the clinician, who must determine whether the complaints are related to the normal aging process, sleep hygiene issues, or the presence of pathology.[59,60] Problems with sleep are widespread among elderly persons, with 25% to 40% complaining about sleep difficulties. There is no evidence to confirm the widely held belief that the need for sleep declines with age. However, sleep quality decreases, and the frequency of various primary sleep disorders increases. The most common age-related change in sleep pattern is a striking increase in the number of nocturnal awakenings, resulting in lower total sleep time and lower sleep efficiency (total sleep time/time in bed). Whether sleep latency changes with aging is equivocal. The amount of time spent in stage 1 nonrapid eye movement (NREM or light) sleep tends to increase with age. The decrease in total sleep time at night is associated with an increase in unwanted daytime naps. Disrupted sleep in the elderly is, in large part, explained by medical and psychological issues and the lack of structured physical and social activity during the day. Chronic illnesses, nocturia, medication and alcohol use, periodic leg movements, bereavement, and depression also play a role. Not surprisingly, the elderly are more likely to use sedatives or hypnotics; their use is more frequent in elderly women than in elderly men. While hypnotics and sedatives are occasionally necessary, their chronic use may contribute to sleep disruption and aggravate certain sleep disturbances, such as sleep apnea. Increased autonomic activity, increased sensitivity to external stimuli (which may increase arousals as a result of environmental factors), decreased exposure to outdoor light, inactivity, and daytime napping also play a role in sleep disruptions in the elderly. Alterations in endogenous circadian rhythms for variables like temperature and cortisol or thyroid-stimulating hormone (TSH) levels also may contribute to sleep disruption in the elderly.

The neural system that regulates sleep is, like most other systems, subject to the aging process, and sleep disruption occurs in the elderly in the absence of any pathologic process. The amount of stage 3 and 4 sleep (slow- or delta-wave sleep) declines with aging, although some argue that the aging decline is mostly a technical issue related to how delta-wave amplitude is defined. Changes in slow-wave sleep appear to be evident early, perhaps by 20 years of age. Arguments have been made both for and against declines in the amount of REM sleep with age. The persistent controversy about REM sleep and aging suggests that if REM sleep does change with aging, the magnitude of decline is so small that it does not overwhelm the confounding factors in studies.

Sleep disorders such as sleep apnea and restless limb syndrome, with periodic limb movements, appear to be more prevalent in older persons, and they are also marked more among nursing home residents than the independent elderly. For example, using an apnea index of five per hour as a threshold, one study found evidence of sleep apnea in 42% of elderly nursing home residents, in contrast to 24% of the independent elderly. A community-based study of individuals aged 71 to 87 showed a 55% prevalence of sleep-disordered breathing that was documented by polysomnography, including 38% obstructive sleep apnea and 17% central sleep apnea.[61] However, longitudinal follow-up of these individuals did not show an independent correlation with either cardiovascular disease or mortality.

INTERPRETING PULMONARY FUNCTION TESTS IN THE ELDERLY

Several issues complicate the interpretation of lung function tests in the elderly, as reviewed by Vaz Fragoso and Gill.[62] The elderly are not well represented in most reference value reports; the number of subjects usually falls off significantly after age 60. The number of subjects over age 80 is usually so small that mean values calculated from regression equations are essentially an extrapolation of the data for younger persons. This means that the average or "predicted" value may not be as representative for the elderly as it is for middle-aged persons. The fall in sample size with aging likely reflects the reduced total number of candidates for participation and the larger number of individuals who fail screening criteria. In reference value studies, individuals are screened so as to be free of symptoms and illnesses that alter lung function. These selection criteria may eliminate more older, than younger, candidates because of their increased prevalence of illness. Also, test quality is carefully standardized. Cognitive impairment may compromise test quality. As a result, older individuals may have more difficulty meeting test quality criteria, increasing their likelihood of exclusion and potentially increasing the variability of reference data for the elderly. In summary, the selection processes may make the older individuals who participate in reference studies less representative of the individuals who present for clinical lung function testing.

These same issues also affect the limits applied to determine whether a tested individual is within the "normal" range. Limits are often defined assuming that the distribution of data is Gaussian. Although tests of this assumption are sparse, there is reason to suspect that it is more likely to fail in the elderly. Even when the "normal" range is defined using methods that avoid assumptions about data distribution, data from the elderly are often lumped with those of the younger subjects. The result may be an erroneous "normal" range. All these reference value issues suggest that increased caution should be used in interpreting lung function tests in the elderly. This caution is especially important for those over age 80 and in any elderly person whose data lie near the limits of a "normal" range.

UNRAVELING THE BIOLOGY OF THE AGING LUNG

Many questions remain about how the lung ages and how this affects the development of chronic age-related disease (such as pulmonary fibrosis and COPD). The National Institutes of Health and interest groups have named seven "pillars of research" in the biology of aging including inflammation, adaptation to stress, epigenetics, cellular metabolism, macromolecular damage, proteostasis, and stem cells/regeneration.[63] Model organisms (such as yeast, worms, and flies) and vertebrate models (primarily mice) have begun to address these key aspects clarifying what factors accelerate or protect against aging and how aging drives lung disease pathogenesis that will likely result in clinical impact. To connect molecular and cellular changes that occur within the aging lung, Angelidis et al. integrated single cell transcriptomic and proteomic data of a mouse lung aging model (3 months vs. 24 months old), showing an increase in proinflammatory pathways, reduction in mitochondrial function, and altered extracellular matrices.[64] Modeling of aging is important in preclinical testing and comparative studies of human disease. Ongoing research efforts are critical to model development and understanding lung aging.

CONCLUSIONS

As the aging population grows, it becomes increasingly important to understand the aging lung and its function. At the cellular level, the processes central to aging are thought to include inflammation, adaptation to stress, epigenetics, cellular metabolism, macromolecular damage, proteostasis, and stem cells/regeneration. Pathologic changes in these homeostatic processes result in changes to airway and parenchymal structure and abnormal respiratory system physiology. Understanding normal aging in the lung may potentially inform management and treatment of diseases of accelerated aging such as COPD and pulmonary fibrosis.

As this chapter is being written, the world is gripped by a pandemic caused by a novel respiratory coronavirus, SARS-CoV-2 (COVID-19). There are marked disparities in risk of symptomatic, severe, critical, and fatal disease among people with various comorbidities and ethnicities. Chief among the determinants of risk is age (and, particularly, advanced age). Many factors may contribute to the age-related risk. Additional investigation is necessary to increase our understanding of how these specific factors impact disease pathogenesis and improve our treatment and control of current and future respiratory disease outbreaks.

CHAPTER 19

Innate and Adaptive Immunity in the Lung

Clemente J. Britto
Charles S. Dela Cruz

INTRODUCTION

The lung is constantly exposed to environmental nonpathogenic and pathogenic moieties in ambient air. These moieties include infectious agents or their products, allergens, irritants, and other inhaled antigens capable of eliciting an immune response. The first line of defense in the interactions between environmental exposures and the respiratory tract is a barrier composed of a mucus layer, airway surface liquid, cilia, and the airway epithelium. This barrier is supported by a complex network of immune defense mechanisms that are both innate and adaptive.[1,2] The immune response must recognize and react to a wide variety of stimuli. It must also identify and eliminate unwanted pathogens to keep pulmonary structures free from infection. On the other hand, this response must be closely regulated to maximize pathogen clearance while minimizing excessive inflammation and tissue injury. An adequate balance between immune response and its resolution is essential to preserve normal pulmonary architecture, especially the highly vascular and fragile alveolar epithelial surface required for gas exchange. The disruption of these lung protective mechanisms contributes to the pathogenesis of many pulmonary diseases. Therefore, understanding innate and adaptive immune responses in the lung is important to understand the pathophysiology and to improve the management of respiratory diseases. These anatomic and immune defenses are reviewed below.

ANATOMIC MECHANISMS

The lung's extensive surface area creates an opportunity for frequent and numerous inhaled environmental challenges that include infectious agents, irritants, and fine particulate matter (Fig. 19-1). The alveolar and capillary membranes are critical for gas exchange and must be defended from the noxious effects of these challenges and the immune response they elicit. Unchecked, these exposures can cause excessive inflammation, tissue injury, and the propagation of infection. In turn, unchecked inflammation and tissue damage can lead to anatomic distortion, functional impairments, and abnormal fibrotic repair that compromise gas exchange. Air is inhaled through the nose or the mouth into the extrathoracic portion of the trachea before it enters the thorax. The air is filtered of large particulates by vibrissae (nasal hairs) in the nasal passages and subsequently warmed and humidified as it flows through the nasal turbinates. The nasal secretions lining the airway mucosa contain immunoglobulins (such as secretory immunoglobulin A, sIgA), mucins, and host defense peptides and proteins that facilitate mucociliary clearance, inactivate invading pathogens, and modulate innate immune responses. For example, sIgA accounts for 15% of the total protein in upper airway secretions and plays a significant role in neutralizing and preventing epithelial attachment of invading viruses and bacteria, while host defense proteins and peptides such as lysozyme, cathelicidins, and defensins perform antibacterial, antiviral, and immunomodulatory roles.[3] The airway mucosa is coated, with viscous fluid and mucus secreted by Clara cells, goblet cells, and bronchial glands (Fig. 19-1). This fluid makes up an important airway surface lining that protects the bronchial epithelium and forms a barrier between the environment and the lung parenchyma.

INNATE IMMUNITY IN THE LUNG

The innate immune response is an evolutionarily conserved system of host defense present in multicellular organisms. The purpose of the innate immune system is to provide a rapid response, in contrast to the adaptive immune system, which provides a more specific response but takes longer to respond (discussed later). Because humans breathe approximately 10,000 L of air per day (12 to 15 breaths per minute ×~500 mL tidal volume), we are constantly exposed to pathogens (e.g., viruses, bacteria, and fungi), allergens (e.g., house dust mites, dander), and toxins (e.g., cigarette smoke, pollutants). The innate immune system allows humans to respond to these stimuli even if they have not been primed for a specific response.

Similar to other mucosal surfaces (e.g., gut and skin), innate immune responses must be sequential and balanced. Ideally, this sequence should include: (1) pathogen recognition, (2) initiation of an appropriate response, typically manifested by inflammation, and (3) resolution of inflammation. An inappropriately regulated innate response contributes to the pathogenesis of lung diseases as diverse as asthma, chronic obstructive pulmonary disease (COPD), and interstitial lung disease.

The most important property of the innate immune system is its response to pathogens regardless of whether there has been a prior exposure. Thus, acquired immunologic memory against the pathogen is not required. The anatomic and antimicrobial structures that prevent infection and injury noted above can be thought of as part of this innate response. Therefore, one of the most important roles of the lung innate immune system is its function as a barrier to inhaled pathogens.[4,5] The tight junctions formed between neighboring cells create a barrier that prevents pathogen entry (Fig. 19-1). In addition to this barrier function, the epithelium has a coordinated system for the removal of inhaled pathogens and cellular debris. Goblet cells and secretory glands produce mucus that traps pathogens. A coordinated system of ciliated cells moves mucus up the mucociliary escalator to be expectorated during coughing. A disturbance in these essential functions may lead to pathology. In primary ciliary dyskinesia (PCD), ciliary function impairments result in bronchiectasis and recurrent bacterial infection.[6,7] In cystic fibrosis (CF), abnormal epithelial chloride and bicarbonate transport disrupts airway surface liquid homeostasis, preventing effective mucus clearance that leads to chronic inflammation, bronchiectasis, and recurrent bacterial infections.[8–11]

The mucociliary escalator is particularly effective for large particles, but smaller particles (<5 μm) can travel to the distal alveolar epithelium. Here, instead of mucociliary clearance, particles encounter secreted surfactant proteins (specifically SP-A and SP-D; also known as pulmonary collectins) that act as opsonins and assist resident macrophages in phagocytosis.[12] Finally, throughout the respiratory tract the epithelium secretes numerous innate immune antimicrobial molecules with their own antimicrobial, ion transport, and immunomodulatory activity that modulate cellular responses to infection.[13,14]

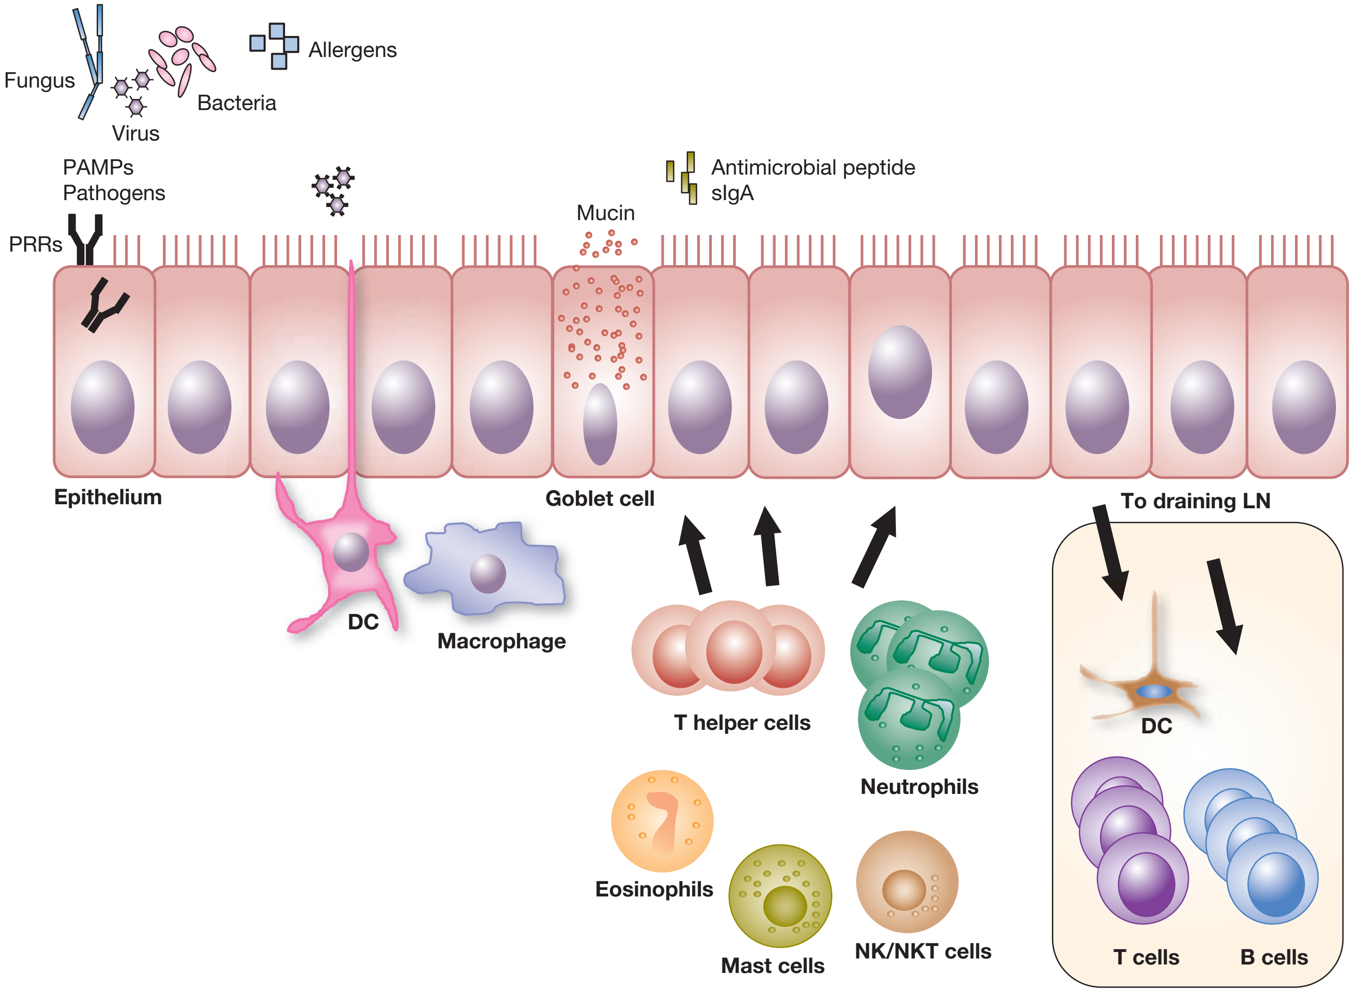

Figure 19-1 Innate recognition of pathogen or PAMPs on airway epithelium. Pathogens such as fungus, virus, or bacteria (or their associated pattern-associated molecular proteins, [PAMPs]) and environmental allergens are first detected by membrane-bound, cytosolic, and/or endosomal innate sensors or pattern recognition receptors (PRRs). The respiratory epithelial cells provide a physical barrier between the airway luminal antigens and the underlying respiratory tissues in their control of immune defense and tolerance. Specialized epithelial cells can have cilia, produce a mucus layer, and secrete antimicrobial proteins and secretory IgA (sIgA) that limit pathogen exposure to the epithelial cells. Dendritic cells (DCs) interdigitating between and lying near the epithelium, as well as tissue macrophages, are well positioned to sample and ingest incoming antigen. Recognition of the antigen by the innate immune receptors leads to production of proinflammatory cytokines and chemokines, which recruit immune cells such as neutrophils, T cells, NK cells, NKT cells, eosinophils, or mast cells. Activated DCs that have taken up the inhaled antigen migrate to nearby draining lymph nodes. In the lymph nodes, the DCs help integrate the signals from the inhaled substance and the innate immune response into signals that direct cells of the adaptive immune system. The DCs encounter appropriate naïve CD4$^+$ T cells where factors such as the phenotype of the antigen-presenting cells (APCs) and cytokine milieu modulate differentiation of CD4$^+$ T cell subsets with their characteristic cytokine and functional profiles. These immune cell functions and cytokine production determine whether an activating or a tolerant response will develop.

PATHOGEN RECOGNITION

The innate immune response enables the host to respond to a wide array of pathogens. Foundational discoveries in the field of innate immunity suggested that the host detects and responds to these pathogens through receptors that recognize conserved sequences called pathogen-associated molecular patterns (PAMPs), which exist in pathogens and are not present in the host (Fig. 19-2).[15,16] Experiments in *Drosophila* (fruit flies) in 1996 identified pattern recognition receptors (PRR) that recognized PAMPs and supported the concept of innate receptors.[17] Subsequently, PRR were identified in humans,[18] and more recently, additional PRRs have been shown to recognize not only exogenous PAMPs, but also endogenous molecules released from damaged cells, referred to as damage-associated molecular patterns (DAMPs).[19,20] The major types of PRR are described below.

■ Toll-like Receptors

The mammalian Toll-like receptor (TLR) family received its name from the *Drosophila* Toll gene. Early studies that involved the genetic manipulation of Toll resulted in dramatic defects in innate immune responses.[17,21] Since this discovery, the TLRs are appreciated to be the prototypical PRR molecules.[18,22] TLRs are present on the cell surface, in cytoplasm, or in endosomes (intracellular vesicles). As a group, they are characterized by N-terminal leucine-rich repeats that recognize pathogens, a transmembrane region, and a cytoplasmic domain that is highly homologous to the interleukin 1 (IL-1) receptor and the IL-18 receptor.[23] To date, 10 TLRs have been identified in humans, with different TLRs recognizing distinct PAMPs.[24,25] In general terms, TLR recognition of PAMPs is based upon cellular compartmentalization. Recognition of viral RNA and DNA occurs in intracellular vesicles by TLR3, TLR7, TLR8, and TLR9. In addition,

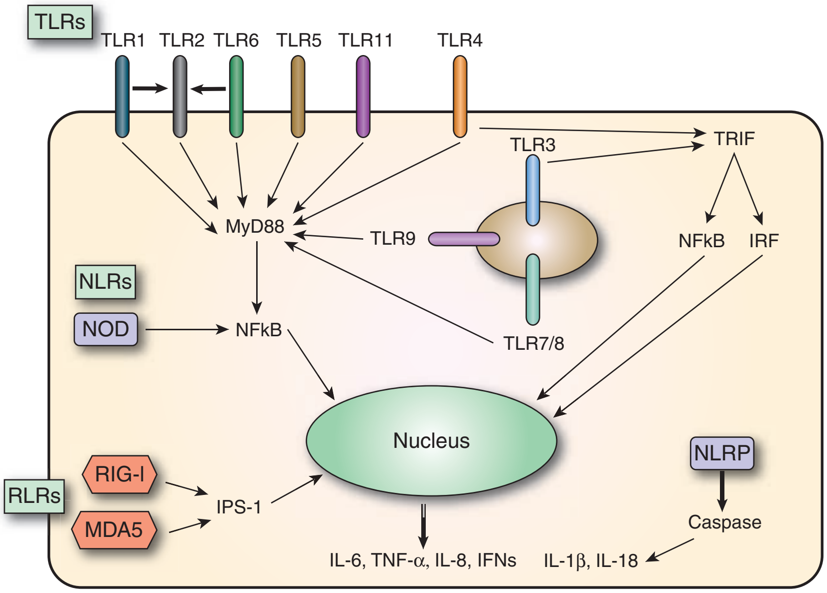

Figure 19-2 Pattern recognition receptors (PRRs). Classes of PRRs include Toll-like receptors (TLRs), retinoid acid–inducible gene-I-like receptors (RLRs), and nucleotide oligomerization domain–like receptors (NLRs). Not shown are C-type lectin receptors (CLRs). TLRs, RLRs (e.g., RIG-I, MDA5, other sensors), and NLRs (e.g., NOD1, NOD2, NLRP3) are innate immune sensors that recognize danger signals derived from pathogens (PAMPs), damaged cells (DAMPs), or associated nucleic acids at the cell surface, in endolysosomes, or in the cytoplasm. Signaling by these sensors promotes either the activation and nuclear translocation of transcription factors (IRFs, NFκB, and AP-1) that drive expression of cytokines (IFN-α/β, TNF, and pro-IL-1β), or the assembly of the caspase-1 inflammasome and subsequent maturation of IL-1β from pro-IL-1β. IFN, interferon; IL, interleukin; IRFs, interferon regulatory factors; MDA5, melanoma differentiation-associated gene-5; NFκB, nuclear factor κB; NLRP, NLR with a pyrin domain; NOD, nucleotide oligomerization domain; RIG-I, retinoid acid–inducible gene-I; TNF, tumor necrosis factor; TRIF, TIR-domain-containing adapter-inducing interferon-β.

TLR7 and TLR9 recognize RNA and DNA, respectively from bacteria, protozoa, and fungi. One unique characteristic of TLR4 is its localization on the cell surface and in endosomes,[26] and thus TLR4 recognizes viral proteins in addition to bacteria, protozoa, and fungi. TLR2, which is present on the cell surface, also recognizes viral proteins. TLR2 and the remaining TLRs, which are also surface receptors, recognize bacteria, parasite, fungi, and host proteins (e.g., DAMPs) (Table 19-1; Fig. 19-2).[25,27–29]

TABLE 19-1 Toll-like Receptors (TLRs)

TLRs	PAMP	Cellular Location
TLR1	Lipoprotein (bacteria)	Plasma membrane
TLR2	Lipoprotein (e.g., bacteria, viruses, parasites, host damage)	Plasma membrane
TLR3	dsRNA	Endosome
TLR4	LPS (bacteria, virus, host damage)	Plasma membrane
TLR5	Flagellin (bacteria)	Plasma membrane
TLR6	Lipoprotein (bacteria, virus)	Plasma membrane
TLR7 (human TLR8)	ssRNA (virus, bacteria, host damage)	Endosome
TLR9	CpG-DNA (virus, bacteria, protozoa, host damage)	Endosome
TLR10	Unknown	Endosome
TLR11	Profilin-like molecule (protozoa)	Plasma membrane

TLR Signaling Pathways

PAMP recognition by TLRs stimulates signaling pathways that ultimately lead to transcriptional activation and protein synthesis. The responses that are elicited can be cell type specific. They also utilize two distinct pathways based on which of two adaptor molecules they employ: (1) myeloid differentiation primary response gene 88 (MyD88) and (2) TIR-domain-containing adapter-inducing interferon β (TRIF).[30,31] With the exception of TLR3, MyD88 is activated for the downstream signaling of TLRs. MyD88 interacts with the IL-1R-associated kinase (IRAK)-4, and other IRAK family members, before they dissociate from MyD88 and interact with TNFR-associated factor 6 (TRAF6). IκB kinase (IKK)-β and MAP kinases are then activated, leading to another complex of IKK molecules that are degraded and release nuclear factor kappa light chain enhancer of activated B cells (NF-κB). NF-κB is a critical transcription factor for TLR-induced genes in inflammation. In addition, activation of the MAP kinase cascade leads to another transcription factor, AP-1, which is associated with activation of cytokines. TRIF-dependent signaling is responsible for TLR3 signaling and in endosomal TLR signaling.[32] TRIF interacts with TRAF3 and TRAF6 and leads to tumor necrosis factor (TNF) receptor (R)-associated death domain protein (TRADD), ultimately leading to activation of NF-κB. Downstream from TRIF is activation of interferon regulatory factors (IRFs) that induce the expression of interferons and interferon-stimulated genes.

RIG-I-Like Receptors

The RIG-I-like receptor (RLR) family presently includes three members: retinoic acid-inducible gene I (RIG-I), melanoma differentiation-associated factor 5 (MDA5), and laboratory of genetics and physiology 2 (LGP2) (Table 19-2).[33,34] RLRs are constitutively expressed by all nucleated cells, suggesting a central role in innate immune recognition and response to viral infection. A measure of their importance can be seen in the evolution of viral mechanisms to evade or suppress RLRs.[35–37] In the 1950s, interferons (IFNs) were discovered to be a critical antiviral innate immune response to viral infection produced by infected cells, and important in the recruitment and activation of lymphocytes (e.g., NK and CD8+ T cells) that recognize and kill virus-infected cells.[38] While the presence of an intracellular TLR receptor for dsRNA was hypothesized in 1969,[39] and subsequently identified, the discovery of RLRs introduced a

TABLE 19-2 RIG-I-like Receptors (RLRs)

RLRs	PAMP	Cellular Location
RIG-I	Short dsRNA	Cytoplasm
MDA5	Long dsRNA	Cytoplasm
LGP2	Unknown	Cytoplasm

second family of PRRs that are cytoplasmic sensors of viral nucleic acids that contribute to antiviral host defense by inducing interferon production. RIG-I was initially discovered in 1997 as a gene induced in acute promyelocytic leukemia cells after stimulation with retinoic acid.[40,41] Several years later, RIG-I was found to be activated by interferon.[42] Similarly, MDA5 was identified in 1999[43] and was later found to be induced by interferon.[44] LGP2 was suggested to function as a RIG-I inhibitor, exerting a regulatory role on antiviral innate immune responses.[45] Additional experiments suggest that LGP2 may modify viral RNA to assist RIG-I and MDA5 recognition of dsRNA.[24] Three genes encode RLRs in mice and humans, and all share a conserved helicase domain. Structurally, RIG-I and MDA5 are composed of two N-terminal caspase recruitment domains (CARDs), a central DEAD box helicase/ATPase domain, and a C-terminal regulatory domain.[46] LGP2 retains the helicase domain but lacks the CARD domain.[46] Their cytoplasmic location allows for recognition of dsRNA viruses and dsRNA intermediates generated during ssRNA viral replication. In addition, ssRNA from common respiratory viruses (e.g., influenza virus, respiratory syncytial virus, and human metapneumovirus) also may be detected by RLRs.[47] An important adaptation to protect the host from unwanted RLR-induced inflammation and injury is the ability of eukaryotic cells to avoid self-activation of RLRs by RNA in mitochondria, and RNA released into the cytosol through packaging that avoid RLR recognition.[35]

In the human lung, RLRs have been found to respond to a range of respiratory viruses, from rhinovirus to influenza virus. In response to viruses, activation of intracellular signaling ultimately leads to interferon production and the activation of interferon-stimulated genes.[47] RLR signaling is dependent on CARDs, which interact with the interferon-β-promoter stimulator 1 (IPS-1, also known as MAVS, CARDIF, or VISA). IPS-1 is localized on the mitochondrial membrane. IPS-1 activates TRAF3 and TRADD, which are adapter molecules for IFN-inducible gene expression.[24] In addition, NF-κB signaling may also be triggered by RLR-nucleic acid interactions.[48]

NOD-Like Receptors

Nucleotide-1 oligomerization domain (NOD)-like receptors (NLRs) are another family of cytoplasmic pathogen sensors that were discovered in the 1990s.[49] There are more than 20 NLR receptors in this family, which share structural similarity (Table 19-3).[50] Their molecular structure includes: (1) C-terminal leucine-rich repeats, which function to detect microbial patterns; (2) a central NOD domain that initiate self-oligomerization; and (3) the N-terminal effector domain.[51] Based upon this N-terminal structure, the NLRs are subsequently classified into four groups (NLRA, NLRB, NLRC, NLRP).[50] NLRs activate important signaling pathways mediated by NF-κB and MAP kinases and activate caspases. The result is activation of diverse signaling pathways that induce innate immune responses.[52,53]

NOD1 and NOD2 identify bacterial PAMPs by recognition of peptidoglycan from Gram-negative bacteria, Gram-positive bacteria, and mycobacteria.[50] The importance of NLRs was highlighted by the evidence that NOD polymorphisms are associated with increased severity of atopy, eczema, and asthma,[54] as well as other inflammatory diseases (e.g., Crohn's disease,[55] tuberculosis,[56] and lung cancer[57]). This suggests that a defect in bacterial clearance may influence the host microbiome and subsequent pathophysiology of disease. Distinct from NOD1 and NOD2 are a group of NLRs that activate caspases such as caspase-1. Caspase-1 is the prototypical caspase required for cleavage and processing of inflammatory cytokines (IL-1β, IL-18) into their active forms.[58] This signaling pathway is now commonly referred to as the "inflammasome," and has been shown to be critical for effective innate immune responses against a wide range of microbial pathogens, cancer, and inflammatory, metabolic, and autoimmune diseases.[59] Specific to the lung, the inflammasome is critical for responses to important pathogens such as influenza A virus,[60,61] *Streptococcus*,[62,63] *Pseudomonas aeruginosa*,[64] and *Mycobacterium tuberculosis*.[65] In addition, activation of the inflammasome has been suggested to contribute to the pathogenesis of asthma,[66] chronic obstructive pulmonary disease (COPD),[67] cystic fibrosis,[68] and pulmonary fibrosis.[69]

TABLE 19-3 NOD-like Receptors (NLRs)

NLRs	PAMP	Cellular Location
NOD1	Gram-negative > Gram-positive bacteria	Cytoplasm
NOD2	Gram-negative, Gram-positive bacteria, mycobacteria	Cytoplasm
NLRP 1–14	Viruses, bacteria, mycobacteria	Cytoplasm

C-type Lectin Receptors

The C-type lectin receptors (CLRs) were identified in the early 1900s and represent a diverse family that includes more than 1000 members.[70] The CLRs were initially characterized as Ca^{2+}-dependent (C-type) carbohydrate-binding (lectin) proteins[70] but, subsequently, some CLRs were found to not bind carbohydrate ligands or require Ca^{2+}-dependent signaling.[71] Currently, CLRs have been classified into 17 groups.[71] Structurally, CLRs are characterized by a carbohydrate-recognition domain (CRD) that is highly conserved.[70] Despite this conserved CRD structure, CLRs are involved in cell functions as diverse as adhesion, repair, endocytosis, and phagocytosis, as well as innate immune pathogen recognition.[72] CLRs recognize a wide variety of pathogens including viruses, bacteria, and fungi. Several of the canonical CLRs include dectins, mannose-binding lectin receptors, and surfactant protein. Dectin-1 and Dectin-2 are important PRRs for recognition of fungi.[73] Upon recognition of fungal PAMPs, intracellular signaling pathways involve activation of NF-κB and MAP kinases.[74]

Mannose-binding lectin (MBL) receptors function as PRRs by recognizing carbohydrate motifs on pathogens, which leads to complement activation.[23] MBLs recognize diverse pathogens that include Gram-positive and Gram-negative bacteria, yeast, parasites, mycobacteria, and viruses.[75] Surfactant protein (SP) was first identified as a critical phospholipid for decreasing alveolar surface tension to prevent atelectasis.[76] However, in the 1980s after the discovery of MBLs, sequencing of SP revealed significant structural similarities.[77] In accord with these similarities, SP-A and SP-D, secreted by alveolar epithelium, are considered collectins, and have been shown to function as agglutinins, opsonins, and inflammatory modulators[12] in response to viruses, bacteria, mycobacteria, and fungi.[78,79]

PATHOGEN-INDUCED INNATE IMMUNE RESPONSES

Inhaled pathogens may circumvent the mucociliary escalator on the airway epithelium, which, along with mucus and airway host defense proteins, form the first barrier against respiratory pathogens by virtue of their location and distribution. Antigen-presenting cells (APCs) such as dendritic cells (DCs) serve a critical role for pathogen recognition by extending projections into the airway between epithelial cells to sample the environment. On both airway epithelium and DCs, there is a wide repertoire of PRR that recognize pathogens.[80] Upon PAMP recognition, PRRs activate signaling pathways that lead to subsequent inflammatory responses. An important component of this inflammatory response is the production of chemokines to recruit immune cells (e.g., neutrophils, eosinophils, macrophages, and lymphocytes including natural killer [NK] and NKT cells) that are critical effectors for the initiation and resolution of inflammation. In addition to chemokine production, PRR activation stimulates the production of cytokines (e.g., TNF-α, IL-1β, IL-6, transforming growth factor β [TGF-β], IL-10) that activate effector cells and contribute to the regulation of innate and adaptive responses in the lung.[80] PRR activation influences the balance of oxidation and proteases present in the lung. Importantly, dysregulation of oxidation has been shown to contribute to the pathogenesis of COPD,[81] while defective antiprotease activity, best exemplified by α-1 antitrypsin deficiency, is a significant risk factor for the development of asthma, bronchiectasis, and emphysema.[82]

Human host defense (or antimicrobial) peptides and proteins such as cathelicidins, defensins, lysozyme, cystatin, PLUNCs, and others, are also produced by epithelial cells and recruited immune cells, in response to PRR activation (Fig. 19-1).[83] In humans, two significant groups of host defense peptides are the cathelicidins[84] and defensins.[83] These small cationic peptides have antimicrobial activity against Gram-negative and Gram-positive bacteria, fungi, parasites, and viruses.[85] Epithelial cells and immune cells (e.g., neutrophils) produce both cathelicidins and defensins, and in addition to their antimicrobial properties, these peptides participate in immune modulation, influencing adaptive immune responses and wound repair.[84,85] Therefore, host defense peptides and proteins are an excellent example of an innate immune response, initiated by PRR recognition of pathogens or PAMPs, which results in a protective response, regulates inflammation, and bridges innate and adaptive immunity.

CELLULAR RESPONSES IN THE LUNG

When pathogens bypass the initial lung mucosal barriers, the host's immune system responds with a coordinated defense program that involves specialized cells that target the threat, neutralize it, and dispose of remnants that may cause tissue injury. Macrophages are phagocytes that engulf pathogens (viable and nonviable microorganisms), as well as apoptotic and necrotic cells that have undergone physiologic and pathologic cell death.[86] Ultimately, the lung must perform these tasks in a selective manner in order to avoid unnecessary inflammation that can cause continued tissue destruction. The innate immune system, as described above, is made up of a humoral arm (lactoferrins, lysozyme, secretory IgA, surfactant proteins, mannose-binding lectins, and defensins) as well as a cellular arm (alveolar macrophages, dendritic cells, neutrophils, ILCs, etc.) that express numerous PRRs and or phagocytic receptors important for their diverse functions. Details of these critical components are provided below.

■ Macrophages

Macrophages are large mononuclear phagocytic cells. They play an important role in host defense based on their ability to phagocytize inhaled moieties, maintain tissue homeostasis, and function as antigen-presenting cells (APCs), which are important in adaptive, humoral, and cell-mediated responses.[87] Macrophage precursors arise from committed hematopoietic stem cells in the bone marrow and are released into the circulation as monocytes before they differentiate into macrophages and dendritic cells as they migrate into the lung. Tissue-resident macrophages form a specialized population based on their local anatomic location. Once called dust cells for their ability to engulf particulates, alveolar macrophages (AMs), named for their presence in the pulmonary alveolus, frequently contain granules of various exogenous materials.[88] One example is particulate matter such as the black carbonaceous granules seen in lungs from smokers and long-term city dwellers. Routine bronchoalveolar lavage will identify these resident airway and alveolar macrophages. However, pulmonary interstitial macrophages from lung tissue can only be collected by tissue dispersion techniques.[89] Of note, the antigen-presenting properties of AMs are inferior compared to those of DCs.[90]

AMs secrete numerous products (e.g., cytokines, chemokines, peptides) and directly interact with other cells and molecules through surface receptors.[91] AMs have multiple functions that include phagocytosis of cells undergoing apoptosis and necrosis, clearance of ingested pathogens or particulates, routine clearance of surfactant, and suppressing inappropriate inflammation and immune responses to harmless inhaled antigens. Macrophages ingest and phagocytose microbial or environmental particulate matter, which is then enclosed in intracellular vesicular phagosomes that undergo fusion with primary or secondary lysosomes to form phagolysosomes. In these AM vacuoles, intracellular killing takes place through mechanisms that include host defense proteins, degradative enzymes, oxidation, reactive oxygen intermediate generation, and "respiratory burst" known as nicotinamide adenine dinucleotide phosphate (NADPH) oxidase degradation. Macrophages facilitate innate recognition functions through expression of diverse PRRs (e.g., TLRs, NLRs, CLRs) to assist host defense in combating invading pathogens. The recognition and clearance of invading pathogens can also occur via opsonin-mediated phagocytosis through the Fcγ receptors. These receptors allow macrophages to be selective in their response to phagocytosed antigen, minimize damaging effects on normal cells, and limit responses to harmless moieties encountered in the airway.

While AMs have greater respiratory burst capacity than other phagocytes,[92] certain organisms have evolved to evade AMs to improve their growth and survival. For example, mycobacteria prevent the fusion of phagosomes and lysosomes, escaping lysosomal hydrolases, and thus becoming resistant to the effects of macrophages. Some inhaled pathogens such as *Mycobacterium tuberculosis* and environmental particulates such as silica are resistant to AM degradation and remain in intracellular lysosomal vacuoles for the duration of the macrophage lifespan. Macrophages also produce inflammatory cytokines and chemokines to recruit other specialized cells to assist in PRR recognition and host defense, in turn, helping to shape the adaptive immune response that follows.

Lung resident AMs continuously sample inhaled particles and pathogens because of their unique position in the alveolar lumen (Fig. 19-1). Because of this location and the potential to cause harm to surrounding delicate and sensitive lung structures (e.g., alveolar epithelium), alveolar macrophages remain in a quiescent state to limit unnecessary inflammation and injury to nearby structural type I and surfactant-producing type II pneumocytes when they encounter harmless antigens. Compared to AMs, DCs are less capable phagocytes with lower levels of expression of phagocytic receptors such as CD11b. In contrast, AMs generate a less robust proinflammatory cytokine response and can suppress adaptive immunity through their effects on neighboring DCs and T cells. It has been shown that depletion of AMs can lead to exuberant lung inflammation in response to otherwise innocuous antigens.[93] These AMs, when co-cultured with DCs in vitro, can suppress T cell function through the release of factors such as nitric oxide, IL-10, TGF-β, and various prostaglandins.[94] Subpopulations of lung macrophages have been identified in lung and disease using cell markers by flow cytometry and RNA sequencing that are likely to have context-specific roles according to anatomical distribution (airway, interstitial, alveolar), maturity, and immune activation profiles.[95–97] These phenotypic approaches can identify interstitial macrophages (IMs) in well-characterized animal models. There is evidence that AMs and IMs are distinct cell populations with differing functions and that each population contributes to different inflammatory and immune responses in the lung.[98] Because IMs are in direct contact with the lung matrix and other pulmonary connective tissue components, the release of mediators or enzymes by these cells may have greater biologic and/or pathologic effects than those released by macrophages in the alveolar compartment.

Dendritic Cells (DC)

In addition to nonspecific mechanisms of the innate immune system, a complex network of DCs is responsible for mobilizing the adaptive immune response, especially against invading pathogens and unwanted antigens.[90,99] DCs are also important phagocytic cells and, in general, are better APCs than macrophages.[90,100] DCs are critical at bridging innate and adaptive immunity because of their extensive interdigitating extensions that reach between cells to provide a tight surveillance network within intraepithelial and subepithelial structures of the respiratory tract. Through this network, DCs continuously sample the lung microenvironment. Because of their distribution, they are ideally positioned to participate in determining whether an inhaled moiety results in pulmonary immunity or tolerance. DCs express MHC and accessory molecules such as CD80, CD86, and CD40, making them excellent professional APCs to incoming naïve T cells.[101,102] They also express a number of innate immune receptors including TLRs, NLRs, and CLRs for the recognition of various patterned motifs from inhaled antigen and pathogens. Lung DCs also express prostaglandin receptors that affect migratory behavior and cell maturation. They also express receptors that detect DAMP proteins such as uric acid, ATP, and high-mobility group box (HMGB)-1. Their ability to sense, take up, and process incoming molecules, and to migrate to nearby draining lymph nodes for antigen presentation, allows DCs to bridge innate and adaptive immunity in the lung.[100] In the lymph nodes, DCs present MHC peptide antigen complexes to T cell receptors on naïve T cells and, in the appropriate context of co-stimulatory molecules on their cell surface and cytokines in the local microenvironment, naïve T cells are activated and proliferate. In the absence of appropriate co-stimulation or cytokines, DC and T cell interaction can lead to tolerance to an antigen, a mechanism that likely helps to avoid harmful immunologic response to harmless inhaled antigens.

DCs have been divided into several subsets based on their cell surface protein expression, origin, location, and specialized function.[103,104] In mice, three major subsets of DCs have been described: resident conventional DCs (cDCs), plasmacytoid DCs (pDCs), and inflammatory DCs. The resident cDCs express CD11c markers and have been divided into those that express CD11b, and those that are CD11b-negative. At baseline, cDCs expressing MHC and CD11c line the conducting airways and can extend their dendrites into the airway lumen between tight junctions. In murine models, these cDCs can also express langerin (a CLR) and the mucosal integrin CD103. cDCs have good antigen-presentation function. A migratory cDC subset migrates to nearby lymph nodes after capturing inhaled antigen in the airway lumen, while lymphoid tissue–resident cDCs reside in the lymph nodes and spleen and respond to antigen delivered via the draining lymphatics. pDCs are characterized by the expression of the surface marker Siglec-H (a bone marrow stromal antigen 1) and abundance of endosomal innate receptors TLR7 and TLR9, which make pDCs particularly important antiviral effectors because of their type I interferon production in response to viruses and bacterial DNA. Residing in the alveolar space are alveolar DCs, which classically express MHCII and CD11c, and can have CD103 subsets. These alveolar DCs resemble human Langerhans cells.[105]

In response to innate and inflammatory stimuli, DCs increase their numbers with rapid recruitment. These DCs have similar abilities to undergo antigen processing, to migrate to draining lymph nodes, and to modulate naïve T cells for either activation or tolerance. The inflammatory cDCs are normally not present in the lung. However, in the setting of inflammation and or infection, circulating monocyte-derived CD11b$^+$ DCs upregulate CD11c, retain Ly6C, and can rapidly be recruited to the lung as inflammatory cDCs to respond to the stimulus. Comparable subsets of DCs in human lungs have been described such as myeloid types of DC that express both blood dendritic cell antigen (BDCA) 1 or BDCA3 and HLA-DR and plasmacytoid DCs that express BDCA2 and CD123.[104,106–109]

Overall, DCs rely on neighboring structural cells, such as the airway epithelial cells, to influence their type of antigen-specific immune response.[110] This epithelial–DC interaction in the lung plays an important role in immune homeostasis as well as the initiation and transition of innate immunity towards antigen-specific adaptive immunity. Some have proposed that extracellular matrix surrounding epithelial cells and DCs contains chemokines that allow for the activation properties of DCs.[111] Antigen presentation by APCs such as macrophages and DCs is a required priming event for T cell activation to occur.

Neutrophils

Neutrophils are derived from the bone marrow and require granulocyte colony-stimulating factor (G-CSF) for their proliferation and differentiation into their mature form. In times of stress or infection, neutrophils are mobilized from the bone marrow into the blood stream and eventually to sites of inflammation such as the lungs.[112] During this process, neutrophils become activated, generate free radicals, release granule contents such as neutrophil elastases and proteases, and participate in phagocytosis and degradation of invading microbes.[113] Neutrophils are one of the first phagocytes recruited to sites of acute lung disease, but they have a limited life span after their release from the bone marrow and within hours they may be cleared along with the resolution of inflammation or disease process. Lungs are a reservoir of neutrophils under steady state. With infection or injury, the neutrophils are promptly activated and recruited to the alveolar compartment as well as the airways.

In chronic lung diseases, neutrophils can be persistently recruited to the lung. Recruited tissue neutrophils are thought to live substantially longer, up to several days, compared with circulating neutrophils.[114] These neutrophils, which are modulated by the local microenvironment, are important for antipathogen responses, but they can cause significant lung tissue damage when they accumulate over longer time periods and release granule contents in an uncontrolled manner.[115,116] Neutrophils can respond to a number of particulate and soluble stimuli. They also have the ability to be primed prior to exposure to stimuli.[117] For example, neutrophils can be primed, or preactivated, by stimuli such as IL-8, granulocyte macrophage colony-stimulating factor, platelet activating factor, and reactive oxygen species. This process helps prepare neutrophils for subsequent contact with pathogens by extending their life span, upregulating cell surface integrins (such as CD11b), optimizing NADPH oxidase assembly, and prolonging neutrophil functional longevity.[118–120]

Neutrophils play an important role in innate immune responses to infection, as these phagocytic cells also possess an impressive array of microbicidal weapons against invading pathogens that include toxic oxygen radical species and proteolytic enzymes. Local infiltration and tissue accumulation of neutrophils are mediated by chemokines secreted by inflamed tissues. At sites of inflammation, mediators such as IL-1 or TNF-α induce or augment the expression of adhesion molecules on endothelial cells and circulating granulocytes. Intravascular circulating neutrophils undergo significant transcriptomic and functional adaptations as they roll along, anchor on the endothelium, and transmigrate to the lung interstitium and subsequently the alveolar space.[120] Ultimately, inflammation will cease, and with successful containment of pathogens, resolution of inflammation often follows. This resolution of inflammation requires wound healing and restoration of the lung's normal structure and function.[121–123] Mechanisms for resolution of tissue inflammation are not as well established, but include substances such as sphingosine-1-phosphate for restoring endothelial barrier and vascular permeability after endotoxin injury, or natural mediators derived from essential fatty acids such as ω-3 fatty acids with their anti-inflammatory and pro-resolving properties.[124] Cytokines such as IL-10, TGF-β, and IL-1 receptor antagonist also have been implicated as important mediators of inflammatory resolution. An inability to resolve inflammation can lead to chronic inflammation in the lung as seen in a number of pulmonary diseases.

■ Innate Lymphoid Cells

Recently a group of innate immune cells, known as innate lymphoid cells (ILCs), have been recognized to lack specific antigen receptors but can produce an array of effector cytokines.[125,126] These ILCs have morphologic characteristics of lymphoid cells and can respond to a variety of signals and play an important role in immunity against microorganisms, tissue homeostasis, and damaged tissue repair. ILCs have been identified and categorized into the following subsets: ILC1s include IL-15-dependent natural killer cells; ILC2s are characterized by their production of T helper 2 cytokines (IL-5 and IL-13); and ILC3s express the nuclear hormone receptor retinoic acid receptor related receptor (Ror)γt and produce cytokines such as IL-17 and IL-22.[125,127] These ILCs are important in innate immunity and very likely will be discovered to contribute to the development of effective adaptive responses. The function and plasticity of these ILCs have an essential role in tissue homeostasis and disease.[128]

ADAPTIVE IMMUNE RESPONSES IN THE LUNG

An essential prerequisite for a successful host immune response is the ability to discriminate between self and non-self.[129,130] Adaptive immune responses, which can also be described as acquired, refer to antigen-specific immunity that often takes several days to mature and to develop a targeted response to a specific antigen.[131] Ultimately, the goal of this adaptive response is to react with, and subsequently remove, a specific antigen. This type of immunity is one that develops throughout life and is the premise behind vaccination for pulmonary infections caused by pathogens such as influenza virus and *Streptococcus pneumoniae*.[132,133] Classically from an immunologic standpoint, an antigen is defined to be a substance that reacts to antibody molecules or antigen receptors on lymphocytes. For example, B cells recognize antigen through specific B cell receptors (BCRs) (and in this case immunoglobulin), while T cells recognize antigen through specific T cell receptors (TCRs). This recognition is through specific epitopes on the antigen being recognized. For T cells to recognize antigenic epitopes through TCRs, cells recognize peptide epitopes from antigen only when presented by antigen-presenting cells (e.g., dendritic cells, macrophages) in the context of appropriate MHC molecules.

Adaptive immune responses are often divided into two major branches: humoral immunity and cell-mediated immune responses. Humoral immune responses rely on the production of antibodies in response to encountered antigens and are mediated by B lymphocytes. Cell-mediated immune responses involve various immune cells such as T lymphocytes, cytotoxic T lymphocytes, activated macrophages, and/or activated NK cells. Activated macrophages and NK cells destroy intracellular pathogens and stimulate nearby structural cells to secrete cytokines that influence other cells of the immune system. Cytotoxic T lymphocytes (often CD8$^+$ cells) can destroy host cells that display foreign antigens on the cell surface, such as cells infected with viruses or intracellular bacteria, or cancer cells that display tumor antigens.

The adaptive arm of the immune response relies on specific recognition of antigens by B and T lymphocytes. These cells are highly equipped to be specific because of their receptors; thus the immune system can recognize a large number of antigens. The functionality of adaptive immunity is based on specific gene rearrangement that results in the generation of more than 10^{11} different species of antigen receptors on the cell surface of T and B cells.[134–136] In addition to adaptive immune responses, this defense system targets pathogens that have evolved mechanisms to evade or to counteract innate immune responses. Therefore, the adaptive immune response builds upon, is shaped by, and itself shapes innate immune responses resulting in a strong interplay between the innate and adaptive arms of our immune system.[137]

Adaptive immunity helps protect the lungs against not only a range of pathogens, but also environmental inhalants, such as cigarette smoke and dusts, as well as allergens. The adaptive immune response is quite versatile, relies on exquisite specificity, and takes advantage of robust memory. This is especially evident when it comes to countering airborne antigens. It is estimated that our human body can recognize 10^7 or more different epitopes and can make up to 10^9 different antibodies, each with different specificity. These epitopes are antigenic determinants that are part of the antigen that is recognized by the antibodies generated by B cells, or by receptors on B and T cells. To recognize the immense number of different epitopes, the human body produces 10^7 or more distinct clones of both B and T lymphocytes, each with their unique BCR or TCR, respectively.[114,138] Among the large variety of BCRs and TCRs, there is bound to be at least one that has the epitope-binding site capable to recognize any antigen the immune system eventually encounters. Thus, the body can recognize any conceivable antigen it may eventually encounter, allowing for an adaptive immune response. However, only a few B and/or T cells can recognize any one epitope, and these cells require an appropriate stimulus to allow for rapid proliferation. This process typically takes several days to occur. During this time, to achieve an effective and mature adaptive immunity, the invading pathogen could cause considerable damage, which is why innate immune responses are important at the early stage of infection, unless the host has already encountered the antigen before and has developed a specific adaptive immune response against the antigen. In this situation, during a repeated encounter with an antigen, adaptive immunity, which already has an established memory response, will take a shorter period to mobilize the adaptive effector cells to counter the invading antigen.

Most T cells express TCR with αβ variable chains, which permits them to recognize the short peptide epitope of an antigen. Typically, precursor αβ T cells are recruited out of the bone marrow to the thymus. In the thymus, they undergo the process of positive and then negative selection to assure that the resultant T cells appropriately respond to peptide in the context of self-MHC, but not strong enough to cause potentially damaging autoreactivity. It is also during this thymic maturation that the T cells acquire the expression of either CD4 (allowing it to recognize peptide in the context of class II MHC) or CD8 (allowing it to recognize peptide in the context of class I MHC). Of note, only a small fraction, <5% of all precursor T cells, complete this process of thymic education and maturation. These cells become naïve T cells that circulate throughout the host to encounter their specific antigen for antigenic stimulation. Thymus-independent T cells do exist and have been identified in the gut but are less well understood in the lung. However, these cells are limited in their diversity and recirculatory capacity and cannot compensate for the lack of thymus-dependent T cells.[139]

T cell development occurs in the thymus where bone marrow–derived premature naïve T cell precursors congregate.[140–142] These T cells start off as double-negative cells (CD4 and CD8 negative). Upon acquisition of successful rearrangement of α and β TCRs, as well as expression of both CD4 and CD8 (making them double-positive cells), these developing T cells undergo positive and negative selection. Since TCRs recognize antigen only in the context of MHC molecules, T cells must be "educated" to first recognize host MHC. During positive selection, double-positive T cells that can recognize self-MHC are selected for proliferation, and those T cells that do not recognize self-MHC are removed through apoptotic cell death pathways. Positive selection also assures that the appropriate TCR selection will associate with the appropriate CD4 or CD8. For example, TCRs specific for MHC II need to retain CD4 and lose CD8. If the reverse occurs, they will die via apoptosis. The same is true for T cells that are specific for MHC I, which need to retain CD8 and lose CD4. Single-positive thymocytes (either $CD4^+$ or $CD8^+$) undergo negative selection to remove potential autoreactive cells. Those T cells that have high affinity for binding self-proteins presented on self-MHCs are induced to upregulate genes that drive apoptosis, eliminating them in the thymus. However, if they escape this elimination process, they may subsequently react against self-antigens, which can result in autoimmunity.[143] Positive selection identifies T cells that react with self-MHC and self-antigen.[144] Negative selection eliminates those that react strongly with self-MHC and self-antigen. Therefore, a successful T cell differentiation selects for MHC restricted TCRs with low affinity for self-antigens.

The underlying premise of the adaptive immune response that allows the system to recognize an unlimited scope of antigens that the host ultimately can encounter is the generation of antigen receptor diversity through gene translocation and recombination processes.[145] This process helps shape each receptor [either T cell receptors on T cells or B cell receptors, or the immunoglobulins (Ig) on B cells]. The TCRs have α and β chains, where there are many different V and J genes that can make up the TCR α chain, and many V, D, and J genes that can recombine to form the variable TCR β chain. Similarly, BCR undergoes similar gene recombination, including junctional diversity and somatic hypermutation that help generate a wide scope of BCR diversity. In the end, each T or B cell will exhibit a unique receptor capable of recognizing its unique antigen. For B cells, the BCR (Ig) recognizes specific epitopes of the antigen. For T cells, $CD8^+$ or $CD4^+$ T cells will express a unique cognate complementary-shaped peptide that is bound to either MHC class I or MHC class II molecules, respectively.

GENERATION OF AN IMMUNE RESPONSE

Upon cognate recognition of T cells with antigen/peptide presented on MHC molecules on antigen-presenting cells, the activated lymphocytes rapidly proliferate to produce large clonal populations (Fig. 19-3). Circulating memory T cells have the capacity to persist in the host for a long time and become mobilized and reactivated during a repeat encounter with the same antigen. This subsequent exposure of antigen leads to a more rapid and persistent production of effector cells in a process called clonal expansion. This allows the limited T cell number, with the appropriate antigen recognition and specificity, to expand and proliferate when necessary. During adaptive immunity, pathogens encountered in the mucosal surfaces, the lung, and the airway mucosa are transported to draining lymphoid organs where antigen is recognized by naïve B and T lymphocytes, which leads to cell activation. These activated B and T cells proliferate and differentiate into effector cells.

Naïve T cells undergo development and maturation in the thymus and circulate out of the thymus to mucosal surfaces and lymph nodes to encounter antigens.[146,147] APCs, such as macrophages and DCs from the innate immune system, present endocytosed foreign antigen to naïve T cells at local draining lymph nodes. APCs present MHC class II associated peptides processed from pathogens to CD4 T cells that express specific TCR against the particular antigen peptide/MHC complex. The TCR-CD3 complex binds to the antigen peptide MHC complex on APC, and this interaction triggers intracellular signaling pathways that provide the first signal, "signal 1," of T cell activation. Upon a subsequent encounter with the same antigen, memory T cells are reactivated using these same TCR pathways.[146] A second signal, "signal 2," is required to ensure that naïve T cells are responding to foreign antigen. This process involves binding

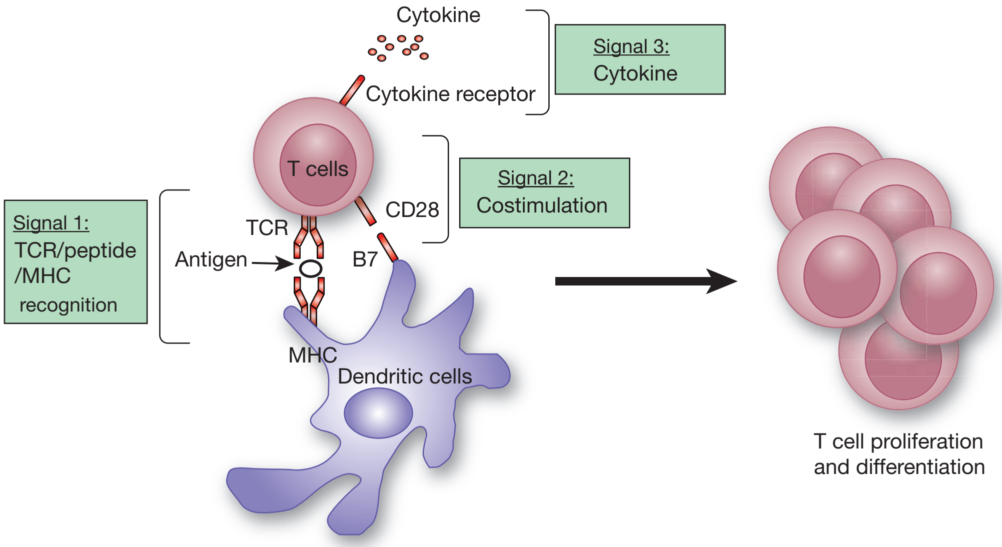

Figure 19-3 Generation of an immune response. Dendritic cells (DCs) and other antigen-presenting cells (such as macrophages) link the innate and adaptive immune response. DCs from the innate immune system present their antigen to naïve T cells at local draining lymph nodes; in the case of the respiratory tract, these are the mediastinal draining lymph nodes. T cell receptor (TCR) ligation to MHC molecules associated with peptides processed from antigen (e.g., pathogen, allergen, toxin) by DCs provides "signal 1." The binding of co-stimulatory molecule CD28 on lymphocyte to CD80 and CD86 expressed by dendritic cells ("signal 2") leads to T cell activation and cell lineage differentiation. "Signal 3" is provided by the polarizing cytokine signals from nearby innate immune cells and local tissue environment. Depending on the type of antigen that is presented and the nature of cytokines in the microenvironment, innate DC cells direct the development of various T helper lymphocyte lineages that play crucial roles in the adaptive immune system.

of CD28 on lymphocytes to co-stimulatory molecules CD80 and CD86 that are expressed only by activated APCs. “Signal 2” leads to T cell lineage differentiation. Without “signal 2,” during the initial antigen exposure, T cells become anergic and are unable to respond to subsequent antigen encounters, a process that avoids or minimizes production of autoreactive cells, and thus autoimmunity against self-antigens. Once T cells are activated by the two signals, only “signal 1” is required for subsequent future activation; an example of this is seen with memory T cells providing a faster immune response. After two-signal activation, T helper cells proliferate and produce multiple cytokines, and this includes IL-2 production for autocrine activation by upregulation of the IL-2 receptor, CD25. “Signal 3” involves polarizing cytokine signaling from innate immune cells that allow for the development of specific types of immune responses.[148] Inflammatory cytokines such as IL-12 can act directly on naïve T cells to provide a third signal, along with antigen and IL-2, to optimally activate differentiation and clonal expansion. CD4$^+$ T helper cells play an important role in mediating various types of immune responses through their cytokine release. There are also other CD4-expressing T cells that are not T helper cells; these include some cytotoxic T cells, NKT cells, and regulatory T cells.

■ Activation of Naïve Helper T Cells

CD4$^+$ T cells play an important role in adaptive immune responses. Proliferating helper T cells that develop into effector T cells can differentiate into one of several lineages (Fig. 19-4).[149] Depending

Figure 19-4 T cell differentiation. Naïve CD4$^+$ T cells differentiate into one of several T helper (Th) cell lineage based on signals from innate immune cells induced by antigenic and inflammatory stimuli as presented by activated DCs. The resultant products of differentiated T cells subsequently help tailor the immune response to various encountered antigen scenarios. T helper cell differentiation is classically regarded as a dichotomy between two main cell types, Th1 and Th2. Th1 cells produce IFN-γ as the signature cytokine and are predominantly involved in cell-mediated immunity against intracellular pathogens. In contrast, Th2 cells do not produce IFN-γ and instead produce IL-4, IL-5, and IL-13. Th2 cells are effective activators of B cell proliferation and antibody production, mediating humoral immunity essential for the eradication of extracellular pathogens as well as mediating allergic-type inflammation. Th17 cells have been described as a distinct T helper subset characterized by the production of IL-17A, IL-17F, and IL-22, contributing to host defense against extracellular pathogens particularly on mucosal surfaces, as well as in the pathogenesis of autoimmune diseases. Recently, more T helper cell subsets have been described, such as Th9 and Th22 cells that participate in allergic-type immune responses. Other stimuli cause CD4$^+$ T cells to become regulatory T (Treg) cells that help dampen immune responses. Other stimuli allow CD4$^+$ T cells to reside in lymph nodes, differentiate into follicular helper T (Tfh) cells, and provide help to B cells. The various T helper subsets require activation of specific master regulator transcription factors such as T-bet, Gata3, Rorγt, Bcl-6, and Foxp3, as well as various STAT molecules for their differentiation as indicated in the diagram. Bcl-6, B cell lymphoma-6; Foxp3, forkhead box p3; ROR, retinoid-related orphan receptor; AHR, aryl hydrocarbon receptor; STAT, signal transducer and activation of transcription.

on the type of antigen that is presented, the strength of the TCR signal, and the nature of cytokines in the microenvironment, innate antigen-presenting cells (typically DCs) direct the development of various T helper lymphocyte lineages. The differentiation of each CD4$^+$ T cell subset is associated with the expression of specific transcription factors that lead to production of an array of cytokines that help orchestrate a specific host response. CD4$^+$ T helper cells, based on their cytokine production, help dictate this type of response. The most studied and established T helper subset is the dichotomy between type 1 and type 2 responses, often called T helper 1 (Th1) and T helper 2 (Th2) responses.

Th1 cells promote cell-mediated immune responses and are required for host defense against viral and intracellular bacterial pathogens. Th1 responses can be characterized by the secretion of IFN-γ, IL-12, IL-10, and TNF-α/β, and stimulation of classically activating macrophages to tackle intracellular pathogens.[150] These cytokines promote macrophage activation, nitric oxide production, and cytotoxic T lymphocyte proliferation, leading to phagocytosis and destruction of microbial pathogens. Th1 responses in the lung are important because alveolar macrophages encounter antigens to activate these specific effector responses. IL-27 signaling in naive CD4$^+$ T cells induce STAT1-dependent expression of the Th1-specific transcription factor, T-bet, which promotes expression of IFN-γ and IL-12 receptors. Subsequent activation stimulates STAT4-dependent IFN-γ production and Th1 differentiation. While Th1 cells are critical for the clearance of intracellular pathogens, exaggerated Th1 responses can result in lung pathology (e.g., autoimmune disease, interstitial lung disease, COPD).

Th2 responses are characterized by production of IL-4, IL-5, IL-9, IL-13, and IL-25, and these cytokines favor antibody production and class switching to IgE and IgG. Th2 cells are required for humoral immunity and play an important role in coordinating immune responses to extracellular pathogens.[151] Th2 differentiation occurs in the presence of IL-4 and either IL-2, IL-7, or thymic stromal lymphopoietin (TSLP). IL-4 stimulates naive CD4$^+$ T cells to induce STAT6-dependent expression of GATA-3, the transcriptional regulator of Th2 cells, which promotes IL-5 and IL-13 expression, and stimulates the expansion of Th2 cells, while suppressing the differentiation of other T cell subtypes. In addition to IL-4-induced activation of GATA-3, IL-2, IL-7, or TSLP is required during Th2 differentiation to activate STAT5, which cooperates with GATA-3 to promote T cell production of IL-4. IL-4 regulates clonal expansion of Th2 cells and, along with IL-13, promotes B cell production of IgE and alternative macrophage activation. Th2 cells also produce IL-5 to stimulate eosinophil activation and survival, or IL-9 to promote mast cell activation. Th2 responses are typically important host immune responses to extracellular pathogens such as parasites or helminths. However, excessive Th2 signaling has been implicated in the development of chronic allergic inflammation and asthma.

T helper 17 (Th17) cells are involved in the immune response against specific fungi and extracellular bacteria.[152] Th17 cells develop from naive CD4$^+$ T cells in the presence of TGF-β and IL-6, cytokines that induce STAT3-dependent expression of IL-21 and the transcription factor RORγt. IL-21 and IL-23 help establish, regulate, and develop (via clonal expansion) Th17 cells. RORγt-induced gene expression leads to the secretion of IL-17A, IL-17F, and IL-22. Cytokines secreted by Th17 cells stimulate chemokine secretion by resident cells, leading to the recruitment of neutrophils and macrophages to sites of inflammation. These cells produce additional cytokines and proteases that further augment immune responses. For human Th17 differentiation, Th17 polarization requires IL-1β, IL-6, IL-21, and IL-23, and is less dependent upon TGF-β. While Th17 cells play a central role in eliminating harmful microbes, persistent secretion of Th17 cytokines can promote chronic inflammation and has been implicated in lung diseases such as COPD, sarcoidosis, and granulomatous diseases. The role of cytokine polarization in lung diseases has been studied in transgenic animal modeling systems where specific cytokines are overexpressed, or cytokine receptors or transcriptional factors such as GATA-3 and T-bet are modified. These studies have helped to elucidate the effector function of individual cytokines and their pathophysiologic consequences in the lung.[153]

T helper 9 (Th9) cells secrete high levels of IL-9, CCL17, CCL22, and, in mouse, IL-10. Th9 cell differentiation requires the presence of TGF-β and IL-4, which induce transcription factors PU.1/Spi-1 and interferon regulatory factor (IRF) 4 that regulate IL-9.[154] Cytokines such as IL-1β, IL-6, IL-21, and type I interferons all enhance Th9 differentiation, and IL-2 and IL-25 promote IL-9 secretion. Different from Th2 cells, Th9 cells do not express IL-4, IL-5, or IL-13. Th9 cells are important for host defense against parasitic and helminthic infections, but they are also associated with the development of chronic allergic inflammation, airway remodeling, and autoimmune diseases.[154,155] T helper 22 (Th22) cells primarily secrete IL-22, IL-13, and TNF-α. Similar to Th17 cells, Th22 cells express IL-22, but in contrast, they express several fibroblast growth factors (FGFs) and do not express IL-17, IL-4 (Th2 marker), or IFN-γ (Th1 marker).[156] Th22 cells differentiate in the presence of IL-6 and TNF-α, and their differentiation is inhibited by TGF-β.[157] Th22 cells can be regulated by the aryl hydrocarbon receptor (AHR) transcription factor. IL-22 secreted by Th22 cells primarily affects epithelial and stromal cells rather than other hematopoietic cells, which lack a functional IL-22 receptor. Th22 cells contribute to allergic inflammation in the lung, but their role in skin immunity is better established.

Another subset of CD4$^+$ helper cells are follicular helper T cells (Tfh), which regulate the development of antigen-specific B cell immunity.[158,159] These Tfh cells help B cells generate antibody-producing plasma cells and long-lived memory B cells. Tfh cells are identified by Bcl-6 (a transcriptional repressor) expression and IL-21 secretion. IL-6 and autocrine IL-21 signaling induce helper T cells to express Bcl-6, which controls Tfh cell differentiation and suppresses differentiation of Th1, Th2 and Th17 cells. These Tfh cells have been implicated in several autoimmune diseases, including systemic lupus erythematosus and Sjögren's syndrome.

The actions of T helper cells are balanced by regulatory T (Treg) cells, a subpopulation of CD4-expressing cells that specializes in suppression of T cell-mediated immune responses.[160,161] Treg cells are identified by their expression of CD25 and the transcription factor Foxp3. Treg cells can regulate and suppress immune responses. They produce cytokines such as TGF-β and IL-10 that have immune suppressive activities. Of note, failure to activate an appropriate T cell response can lead to chronic infection, while exaggerated T cell responses can cause excessive tissue damage and are associated with inflammatory and autoimmune diseases. During lung infections, Th1 may mediate lung damage in response to infection. Thus, downregulation of such Th1 responses may help preserve lung integrity. Th2 responses are known to be important during the wound healing process, but if this response is prolonged and uncontrolled, it can worsen the injury and contribute to fibrosis.

Considering the diverse and important roles helper T cells play in the immune system, it is not surprising that these cells influence the immune response in many pulmonary diseases (more is discussed in other chapters). Helper T cells can make occasional mistakes or generate responses that would be considered harmful. In the worst-case scenario, helper T cell responses may be disastrous and prove fatal to the host. Fortunately, this is a very rare occurrence. The adaptive immune system must achieve a balance of sensitivity in order to respond appropriately to foreign antigens, without responding to host antigens and damaging self. When the immune system responds to very low antigen levels that it should not respond to, a hypersensitivity response, such as seen in airway allergies and autoimmune lung diseases, ensues. There are four general types of hypersensitivity reactions that have been described: Type 1 reactions, such as in asthma and allergic lung diseases, involve IgE antibodies and a Th2 response; type 2 and type 3 hypersensitivity responses involve the role of autoimmune and low-affinity antibodies (and, in some instances, it is felt that Th2 cytokines promote such disorders); and type 4 reactions, also known as delayed-type hypersensitivity, are the result of chronic inflammation and activation of lymphocytes and macrophages, typically a Th1 cytokine response.

■ T Cell Subsets with Innate Immunity Properties

While most conventional T cells have reactivity to specific complexes of major histocompatibility (MHC) molecules and antigen peptides, many other T cells do not fit this paradigm. These innate T cell subsets include natural killer (NKT) cells, γδ T cells, and mucosa-associated invariant T (MAIT) cells.[162,163]

NKT cells are innate T cells that are restricted through the glycolipid α-galactosylceramide when it is presented on MHC class I–like CD1d. These NKT cells express both conventional T cell markers such as αβ TCRs and NK cell markers. These cells are only 0.1% to 0.2% of the circulating lymphocyte population in humans. Two types of NKT cells have been described: invariant NKT (iNKT) cells that express specific invariant Vα-Jα α chain paired with certain Vβ chains, and the more diverse NKT cells that display a diverse αβ TCR pairings. NKT cells can readily produce various cytokines upon encounter with various environmental stimuli that have important roles in mucosal lung immunity.[164,165]

γδ **T cells** are enriched in mucosal and epithelial surfaces such as the respiratory tract and can represent from 8% to 20% of resident pulmonary lymphocytes in the lung and 1% to 5% of the circulating blood lymphocytes.[166–168] These T cells have TCR with γδ chains, rather than the conventional TCR chains. These cells recognize antigens via γδ TCR mediated signaling and can recognize stress ligands such as MIC-A, MIC-B, or ULBP through NKG2D receptors. γδ T cells can also be activated by peptide antigen derived by isoprenoid pathway used by certain microorganisms or by mevalonate pathways in infected cells. γδ TCRs have more limited repertoire diversity, and are considered, at times, invariant because they are only able to recognize limited types of antigens. These γδ T cells have been shown to be important in maintaining normal airway responsiveness or tone, as well as in their immunoregulatory role in numerous infectious and noninfectious diseases in the lung.[166,169] Their role includes maintaining lung tissue homeostasis, providing protective immunity against invading pathogens, tissue healing, and epithelial cell maintenance.

Mucosa-associated invariant T (MAIT) cells are a subset of innate-like T cells that express evolutionarily conserved T cell receptor α chain that is restricted by the nonpolymorphic MHC class I related protein MR1.[170] These cells can be activated by microbial riboflavin metabolite–derived antigens presented by MR1, which distinguishes them from other T cells with αβ. Because the riboflavin pathway is unique to microbes, these metabolites can be considered to be comparable to other microbial molecular patterns.[171] For example, MAIT cells secrete TNFα, IFN-γ, and IL-17 when stimulated with various microbial pathogens, and lacking MR1 (and thus MAIT cells), they have impaired control of lung infections. These cells function to promote monocyte differentiation into dendritic cells during infection that bridges innate to adaptive immunity.[172] Their role in the contribution to human lung diseases is beginning to be described.[173,174]

CONCLUSIONS

The lung is a vast organ comprised of conducting airways, alveoli, and tissue parenchyma that is highly specialized to sample the diverse antigens that we breathe in. The lung is equipped with a well-orchestrated immune system to clear particulate debris and to eliminate inhaled pathogens and toxins to protect the delicate capillary-alveolus barrier system that is critical for gas exchange. The immune system in the lung has evolved complex and diverse innate and adaptive immune responses to accomplish these critical functions of lung homeostasis and host defense.

CHAPTER 20

Macrophages and Lymphocytes in the Lung

Katrina E. Traber
Joseph P. Mizgerd
David M. Center

INTRODUCTION

This chapter describes the macrophage and lymphocyte populations present in the lung, in both the absence and presence of inflammatory stimuli. This distinction may be artificial, as the lung actively interfaces with the aero-environment and thus is constantly exposed to stimuli. While we describe the phenotypes themselves, other chapters cover the inflammatory processes and migratory stimuli that change the inflammatory cell complexion in the lung in disease states. Of greatest importance is to note that there is marked heterogeneity of cell surface markers, secretory products, and macrophage and lymphocyte functions in the lung that, together, represent the overall responses to stimuli and pathogens and the resolution of inflammation. We defer discussion of disease states to other chapters, only peripherally referring to unique roles of specific macrophage or lymphocyte subtypes when important to understanding the phenotypes. Our approach is to divide the chapter into descriptions of leukocyte subtypes of the innate (macrophages and lymphocytes) and adaptive (lymphocytes) immune systems, recognizing that there are many other ways to classify the inflammatory cell populations in the lung. Innate and adaptive immunity are described in detail in other chapters.

LUNG LEUKOCYTES IN THE INNATE IMMUNE SYSTEM

A variety of macrophages and lymphocytes are found in the lung and are discussed below.

■ Macrophages

Macrophages are large mononuclear cells with phagocytic capability that are found throughout the lung airspaces and parenchyma at baseline and during inflammation.[1] These cells are key components of innate immune responses in the lung and manifest diverse functions that are associated with cell location, cell stimuli, and cellular origin. Their functions include: (1) phagocytic clearance of inhaled particles, pathogens, and apoptotic cells; (2) immunologic surveillance, raising an immunologic alarm in the presence of pathogenic but not innocuous stimuli; (3) immune regulation by interfacing with other members of innate and adaptive immune responses; and (4) promoting resolution and repair pathways after an injurious insult. No single macrophage effects all these disparate roles. Rather, macrophage populations are diverse and dynamic; they originate from multiple cell types and retain a remarkable degree of functional plasticity over their potentially long life.[2] Because of this diversity, many classification schemas have been developed to categorize macrophages, based on surface markers, location, and function.[3]

In recent years, especially with the emergence of single cell-based analytic techniques, it has become clear that many of these systems inadequately describe the full breadth of macrophage heterogeneity. Here, we describe lung macrophage population based on primary location—airspace/alveolar vs. interstitial/tissue-resident macrophages—and describe the current understanding of subcategories in each of these regions. This is a rapidly evolving field, and our understanding will likely be further refined in the future.

Alveolar Macrophages

Alveolar macrophages (AMs) are defined primarily by their location in the alveolar space (Fig. 20-1) and their accessibility via bronchoalveolar lavage. Their readily accessible location has made them

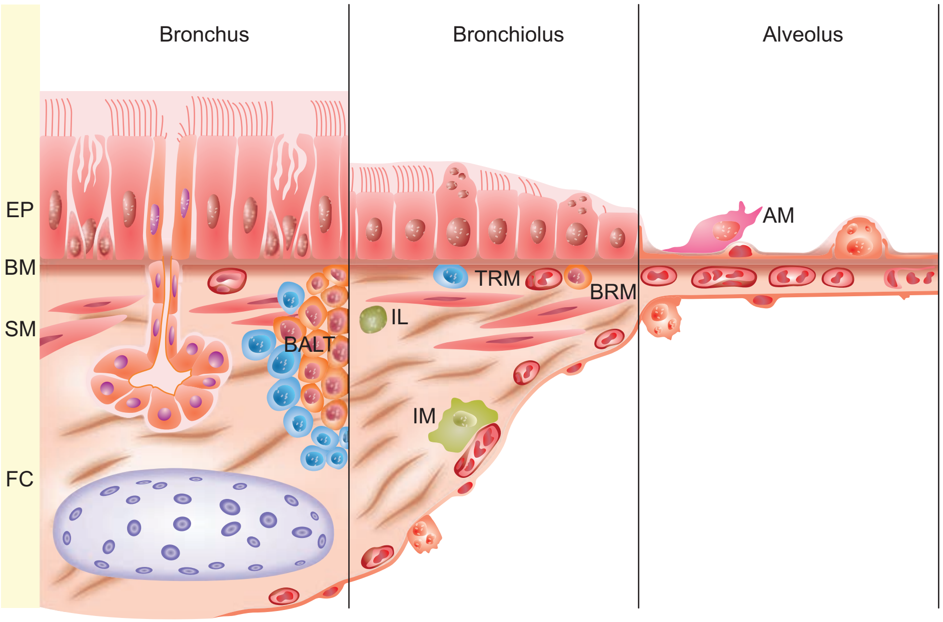

Figure 20-1 Macrophages and lymphocytes are typical components of most lungs. The conducting airways including bronchi and bronchioles are surrounded by loose connective tissue containing diverse leukocytes as well as mesenchymal cells and blood vessels. When organized into tertiary lymphoid structures, lymphocyte aggregates form bronchus-associated lymphoid tissue (BALT) containing both B cells (orange) and T cells (blue), as well as supportive elements like high endothelial venules, fibroblastic reticular cells, and follicular dendritic cells (not depicted). Resident memory T (T_{RM}) cells, including both CD8$^+$ T cells and CD4$^+$ T cells, resident memory B (B_{RM}) cells, and innate lymphocytes (IL), including multiple types of innate T cells and of innate lymphoid cells, are dispersed in these loose connective tissues, often but not always near the columnar epithelial cells and/or blood vessels. Distinct subsets of interstitial macrophages (IM) are found near nerves or blood vessels in the connective tissue. In the parenchyma, alveolar macrophages (AM) are apposed to alveolar epithelial cells on the luminal side. This network of lung leukocytes is key to pulmonary innate and adaptive immune responses to lower respiratory system challenges by infection, allergens, pollutants, or other. (*Modified with permission from Bergofsky EH. The lung mucosa: a critical environmental battleground. Am J Med. 1991;91(4A):4S–10S.*)

TABLE 20-1 Leukocytes of the Innate Immune System: Macrophages

Location	Surface Phenotype[a]	Function	Secretory Products
Alveolar Macrophages Self-renewed; monocyte derived (after infections and injuries)	$CD11b^{-}CD11c^{+}CD64^{+}F4/80^{+}$ $CD24^{-}MHCII^{var}SiglecF^{+}$ various TLR and cytokine receptors; autofluorescent	Direct microbicidal activity; clearance of lipids and cellular debris	Varied; see below
Proinflammatory M1	PAMPs, IFNs, and TLR receptors	Amplification of the anti-infectious inflammatory response	TNF-α, IL-6, IL-1β, chemotactic cytokines for neutrophils and lymphocytes
Proinflammatory M2	IL-4, IL-13 receptors	Amplification of the allergic type response	Arginase, chitinase like proteins, CD36, CD206
Regulatory	IL-10, various proinflammatory stimuli	Control of the local inflammatory response	IL-10, TGF-β, prostaglandins, resolvins
Interstitial Macrophages (IM)	$MerTK+CD64+CD11b+SiglecF^{-}$	Immunomodulatory>>inflammatory	IL-10>IL-6
IM1	$CD11c^{lo}$ $Lyve1^{hi}MHCII^{lo}$ $CD206^{+}$	Subset-specific function not defined, fibrogenic	Poorly defined
IM2 (subset of IM1?)	$(CD11c^{lo}MHCII^{hi})$	Subset-specific function not defined	Poorly defined
IM3	$CD11c^{+}$ $Lyve1^{lo}MHCII^{hi}$ $CD206^{-}$	Subset-specific function not defined	Poorly defined

[a] Surface markers of macrophages vary across species. Table 20-1 highlights mouse data since these macrophage subsets are best characterized in that species.

a well-studied population of lung macrophages in both humans and animal models. In addition, during homeostasis, alveolar macrophages can be identified based on surface marker profiles (Table 20-1) as $CD11b^{-}$ $CD11c^{+}$ $CD64^{+}$ $F4/80^{+}$ $CD24^{-}$ $MHCII^{var}$ $SiglecF^{+}$ autofluorescent cells from mouse lungs[4] or $CD11b^{+}$ $HLA\text{-}DR^{++}$ $CD206^{++}$ $CD169^{+}$ cells from human lungs.[5] However, the specific populations of macrophages residing in the alveolar space vary with inflammatory state of the lung, prior inflammatory experience, and age.

The lungs are populated with macrophages through multiple pathways during embryonic development and early postnatal periods. Much of our knowledge of macrophage origins is the result of fate-mapping and parabiosis techniques. The first macrophages to arrive in the developing lungs are derived from erythromyeloid progenitor cells (EMPs) in the yolk sac.[6,7] These cells widely populate the developing lung, maturing into macrophages without a monocytic intermediate.[7] EMPs also seed the early fetal liver, developing into monocytes that subsequently populate the developing lung.[6] These fetal liver–derived monocytes in the lung migrate to the alveolar space, becoming alveolar macrophages, replacing yolk sac–derived macrophages.[8,9] Development of alveolar macrophages from fetal liver monocytes requires TGF-β[10] and GM-CSF signaling through PPAR-γ.[9,11]

Once established, alveolar macrophages are largely self-renewing.[12] However, in the setting of severe lung injury and significant loss of viable AMs, this population can be renewed by circulating monocytes, as discussed below. Therefore, over a lifetime of stimuli and injury, the pool of AMs gradually and persistently transitions from an initial dominance by cells of embryonic origin towards ever larger fractions of cells derived from marrow-origin monocytes.[13] Distinguishing developmental origins of AMs in humans is difficult, but studies of transplant patients have been revealing. Transplanted lungs retain a large proportion of donor alveolar macrophages for years after transplant,[14,15] establishing their ability to persist without replacement by monocytes. However, in the setting of allogenic bone marrow transplant, where the recipient's alveolar macrophages are ablated, these cells become replaced by monocyte-derived macrophages from the donor, and these cells take on AM surface markers and phenotypes.[16]

The average human cycles thousands of liters of air through the lung daily, which includes particulate matter, innocuous organisms, and potential pathogens. Because of their location at the interface between external air and lung epithelium, a major role of AMs is to clear particulate matter, surfactant, and cell debris. In fact, abnormal AM development secondary to interruption of GM-CSF signaling underlies pulmonary alveolar proteinosis (PAP), which is characterized by progressive respiratory dysfunction secondary to an accumulation of surfactant.[17] In addition, AMs are well positioned to function as the primary immunologic sentinel of the lungs. This process is largely immunologically silent because the bulk of stimuli are nonpathogenic, and inflammatory responses to all of these stimuli would have damaging consequences.

Several mechanisms function to limit AM activation, including the soluble mediators IL10 and TGF-β, surfactant-mediated inhibition of TLR2 and TLR4 signaling, and direct interactions between AMs and epithelial cells.[18] In aggregate, these factors have a much greater effect on AM function than developmental origin of the cells. Of note, adoptive transfer of peritoneal macrophages (PMs) to the alveolar space or AMs to the peritoneal space results in alteration of macrophage phenotype consistent with transfer site.[19] More recently, transcriptomic studies of embryonic derived AMs and monocyte-derived macrophages within the same lungs demonstrated that very few genes differ between these two cell populations.[20] After transfer into the air spaces of the lung, myeloid progeny from induced pluripotent stem cells differentiate to resemble AMs and are sufficient to correct models of pulmonary alveolar proteinosis,[21,22] confirming the cellular plasticity of myeloid cells and the significance of the pulmonary microenvironment in driving the AM phenotype.

Consistent with their role as airway sentinel, AMs must rapidly react to pathogens or other injurious stimuli. Although, as discussed previously, AMs have tonic mechanisms in place to limit activation, AMs also possess an array of surface receptors able to recognize pathogens and inflammatory cytokines. To move AMs into a fully activated state, multiple disrupting events are likely required, such as a decrease in inhibitory signaling after epithelial destruction, plus binding of activating factors to surface receptors.[18] However once activated, AMs play multiple essential roles in pathogen defense (Table 20-1).

First and foremost, AMs can directly clear pathogens through phagocytosis and phagolysosomal killing.[23] AMs also have a significant impact on other members of the innate immune response via the release of proinflammatory cytokines, such as TNF-α, IL-1α, IL-1β, IL-6, and chemokines.[24] These signals lead to the recruitment and activation of several cell types, including monocyte-derived macrophages, to the alveolar space. These monocyte-derived macrophages have a proinflammatory phenotype, producing high levels of TNF-α, neutrophil chemokines, and lysosomal proteases.[25] Alveolar macrophages and monocyte-derived macrophages have distinct transcriptomes and functions in the inflamed lung.[26–28]

Equally important to their role in host-defense, AMs are critical to resolution and repair. After the acute event has been managed, AMs actively stimulate resolution through the phagocytosis of apoptotic neutrophils and injured cells (*efferocytosis*) and the production of anti-inflammatory (e.g., IL-10 and TGF-β) and proresolving (e.g., resolvins, protectins, and maresins) protein and lipid mediators.[29] Monocyte-derived macrophages can undergo apoptosis and be cleared by resident AMs, or they can further differentiate and develop a phenotype nearly indistinguishable from the resident AMs.[20,29] As a result, the overall proportion of embryologically derived AMs is decreased from pre-event levels. Furthermore, these AMs in the resolved lung are reprogrammed, with new baselines and responses to subsequent pulmonary challenges that persist long after the earlier challenges are removed.[28,30,31]

Steady-state alveolar macrophages are long-lived and largely self-renewing, even during inflammation and injury.[32] However, during acute inflammatory events, there is a dramatic influx of monocyte-derived macrophages with a proinflammatory phenotype. Some authors have classified these macrophages as M1 (“classically activated” and stimulated by IFN-γ and LPS, microbicidal, producing TNF-α, IL-6, and reactive oxygen and nitrogen intermediates) vs. M2 (“alternatively activated” and stimulated by IL-4 and IL-13, expressing arginase 1, chitinase-like proteins, CD36, and CD206).[3] However, this classification, while a helpful initial guide to the spectrum of macrophage function, does not apply well to lung macrophage populations.[2,33] Recent, single-cell RNA sequencing analysis of alveolar macrophages before, during, and after an acute inflammatory event demonstrated that while there are subsets of macrophages, they do not conform to the M1 vs. M2 dichotomy, as many cells express markers of both groups.[27]

Interstitial Macrophages (IMs)

In addition to the lung lumen, macrophages are also found in the interstitium of the lung, between the epithelium lining the air spaces and the endothelium lining the blood vessels (Fig. 20-1). Nearly 80% of lung IMs are within alveolar septae, with the remainder residing in connective tissues around conducting airways and vasculature.[34] IMs have been less studied than AMs because they are not readily accessible by lavage.

The early stages of IM development are shared with AMs, as discussed previously, with primitive yolk sac–derived macrophages initially populating the lung, and subsequently replaced by fetal liver monocyte–derived macrophages. Shortly after birth, a final population of macrophages, originating from bone marrow hematopoietic precursors, arrives in the lung and become IMs.[8] Subsequent turnover of IMs appears to be a combination of direct IM replication, and continual seeding from circulating monocytes, which differentiate into IMs.[8,35]

The study of IM function has been limited due to the cells’ location. Until recently, IM function has been studied by stimulating these cells ex vivo, analysis of which can be limited by experimental artifact. However, similar to AMs, IMs are capable of phagocytosis, carry receptors for PAMPs and cytokines on their surface, and are capable of secreting both immunosuppressive (IL-10) and immunostimulatory (IL-6) cytokines.[36,37] Overall, it appears that IMs may have a more immunoregulatory phenotype, secreting higher levels of IL-10, both at baseline and with stimulation (Table 20-1). However, comprehensive studies of IM function in vivo remain forthcoming.

Detailed analysis of IM subsets has become possible in recent years through the combination of advanced flow cytometric techniques that allow for discrimination of IMs and single cell–based methods, such as single-cell RNAseq (Table 20-1). There may be three[38,39] (or two)[40,41] distinct populations of IMs based on current schema. For division of mouse lung IMs (all $\text{MerTK}^+\text{CD64}^+\text{CD11b}^+\text{SiglecF}^-$) into three subsets, CD11c and MHCII levels serve to subdivide ($\text{CD11c}^{\text{lo}}\text{MHCII}^{\text{lo}}$ [IM1]; $\text{CD11c}^{\text{lo}}\text{MHCII}^{\text{hi}}$ [IM2]; and $\text{CD11c}^+\text{MHCII}^{\text{hi}}$ [IM3]). Humans have similar subsets of IMs based on transcriptomes, albeit with divergent surface markers from mice.[39] Other single-cell transcriptomic studies of mouse lungs independently identified two IM subsets: $\text{Lyve1}^{\text{lo}}\text{MHCII}^{\text{hi}}$ vs. $\text{Lyve1}^{\text{hi}}\text{MHCII}^{\text{lo}}$[40] and CD206^- vs. CD206^+.[41] When considered together, all these IM subsets show substantial overlap (IM3; $\text{Lyve1}^{\text{lo}}\text{MHCII}^{\text{hi}}$; CD206^- compared with IM1/IM2; $\text{Lyve1}^{\text{hi}}\text{MHCII}^{\text{lo}}$; CD206^+[41]), suggesting that these studies are detailing comparable subsets of IMs. While all IMs are found in connective tissue (Fig. 20-1), the $\text{Lyve1}^{\text{lo}}\text{MHCII}^{\text{hi}}$ IMs tend to reside near nerves whereas the $\text{Lyve1}^{\text{hi}}\text{MHCII}^{\text{lo}}$ cells tend to be near blood vessels.[40] The latter contribute to fibrotic responses in mouse models,[40] but there remains much to be learned about the unique niches in the tissue, dynamics during inflammation, and distinct functional roles of IM subsets in the lung.

■ Lymphocytes

Growing attention has been paid to subsets of lymphocytes that have antigen receptors of limited diversity or lack antigen receptors entirely and that, instead, respond to stereotypical pathogen products or host-generated alarm signals. Because these cells do not require clonal expansion prior to response, they can respond quickly to stimulus, often with the production of activating cytokines. As a group, these cells are known as *innate lymphocytes* (Fig. 20-1), and they play a crucial role in interaction with other innate effector cells (such as macrophages and neutrophils), as well as adaptive immune responses mediated by T cells, B cells, and dendritic cells. The innate lymphocytes can further be divided into T cells with limited antigen receptor diversity (γδ T cells, iNKT cells, and MAIT cells) and those with lymphocyte morphology, but without antigen receptors (innate lymphoid cells—NK cells, ILC1, ILC2, ILC3, and LTi cells) (Table 20-2).

Innate T Cells

Below we will consider innate lymphocytes that express a T-cell receptor, but of limited diversity, collecively known as innate T cells.

γδ T Cells As suggested by their name, γδ T cells express T cell receptor (TCR) heterodimers containing gamma and delta chains (Table 20-2). While these TCR chains do undergo RAG-directed recombination, the diversity of products is quite limited compared with the αβ TCR. γδ T cell subsets express Vγ1, Vγ4 and Vγ7, in combination with a variety of Vδ chains.[42,43] γδ T cell development branches off from the common thymocyte pathway at the DN2 DN3 stage; therefore, these cells do not express CD4 or CD8.[44]

During lung infections, γδ T cells act as early responders to pathogens. These cells can be stimulated by direct binding of antigen to TCR, binding of PAMPs and DAMPs to TLRs, or direct cytokine stimulation.[45] Activation of γδT cells leads to production

TABLE 20-2 Leukocytes of the Innate Immune System: Lymphocytes

Common Name	Surface Markers	Stimulus	Functions	Products	Location
γδ T cell	Limited γδ TCR CD4$^-$CD8$^-$	Antigen PAMP/DAMP Cytokines	Rapid responders Granuloma formation Protection from injury	IFN-γ IL-17A IL-4	Mucosal barriers
Invariant NKT cell	CD1d; Invariant αTCR Limited βTCR	Lipid antigens (α-Gal-Cer)	Rapid responder Cytokine production Cytotoxic	See subsets below	Marginated in vasculature and interstitium
	Regulator		**Functions**	**Products**	**Location**
iNKT1	PLZF, T-bet		Type 1 responses	IFN-γ	Liver and spleen
iNKT2	PLZF, GATA-3		Type II responses	IL-4	Lung
iNKT17	PLZF, RORγt		IL-17 responses, neutrophils	IL-17	Lung
Mucosal-associated invariant T cells (MAIT)	MR1 Restricted αβ TCR	Riboflavin metabolites IL-18	Rapid responder Cytokine production Cytotoxic	IFNγ or IL-17 or IL-22	Mucosal tissues and vasculature
	Regulator		**Functions**	**Products**	**Location**
MAIT1	PLZF, T-bet		Type I response	IFN-γ	Liver and spleen
MAIT17	PLZF, RORγt		IL-17 response	IL-17, IL-22	Lung
Innate lymphoid cells (ILCs)	No TCR No lymphoid or myeloid markers	Danger and stress signals	Varied	Varied	Varied
	Surface Marker	**Regulator**	**Function**	**Products**	**Location**
NK	CD127$^-$ NKp46$^+$ Eomes$^+$	T-bet	Cytotoxic Effector cell recruitment FAS-mediated apoptosis	Perforin, granzyme, variety of pro- and anti-inflammatory cytokines	Lung parenchyma and airspaces
ILC1	CD90$^+$ CD127$^+$ RORγt$^-$GATA3^{int} Eomes$^-$ NKp46$^+$	Tbet	IL-22, IL-18 receptors	IFN-γ, GM-CSF	Low numbers in resting lung
ILC2	CD90$^+$ CD127$^+$ RORγt$^-$ GATA3^{hi}	GATA-3	“Helper type” Protect against helminths Maintain barrier integrity	IL-5, IL-13	Diffuse; mucosa
ILC3	CD90$^+$ CD127$^+$ RORγt$^+$ GATA3^{int}	RORγt	TH17-type response	IL17, IL22	Non-lung mucosa
LTi	RORγt	RORγt	Induce development of lymphoid tissue	IL17, IL22	Fetal lymphoid tissue

of IL17A and IFN-γ, which have important downstream results, such as effector cell recruitment (macrophage, neutrophil), granuloma formation, and Th17 immune responses. Multiple models of pulmonary infection have demonstrated that γδ T cells increase numbers during acute infection,[46–49] likely due to expansion rather than recruitment.[48] However, experimental depletion of γδ T cells has mixed results, with decreased IFN-γ production and inability to clear pathogen in *Klebsiella*,[50] pneumococcus,[46] and BCG[51] infections, but improved pathogen clearance and increased IFN-γ in a cryptococcus model.[47]

The role of γδ T cells in allergic lung disease has been the subject of investigation. Initial studies in both human asthma and mouse models produced conflicting data regarding whether γδ T cells promoted or inhibited allergic inflammation.[52–54] It now appears that subsets of γδ T cells in the lungs produce IL-4, which leads to enhanced Th2 responses,[55] IL-17, which leads to suppressed Th2 inflammation,[56] or IFN-γ, which inhibits antigen specific IgE. Alteration of the balance of these subsets of γδ T cells, specifically an increase in IL-4-producing and decrease in IFN-γ-producing γδ T cells, was found in patients with allergic asthma[57] or after segmental allergen challenge.[58]

Invariant Natural Killer T Cell (iNKT) Cell Natural killer T cells (NKT cells) are defined by their response to lipid antigens presented by an MHC class I–like molecule, CD1d (Table 20-2). Invariant NKT cells (iNKT, also known as classic or type I NKT cells) express an αβ TCR with invariant α TCR (Vα14-Jα18 in mice, Vα24-Jα18 in humans), combined with one of three β chains (Vβ8.2, Vβ7, or Vβ2 in mice and Vβ11 in humans).[59] Other NKT subsets have been identified, but less is known about them as cell-specific genetic models are lacking and human studies are limited. Hence, we focus the remainder of this section on type I (iNKT) cells.

In mice, iNKT cells make up about 1% to 3% of circulating T cells in mice, and approximately 2% to 5% of lung resident T cells, largely as marginated cells in the vasculature and in the interstitium.[60,61] iNKT cells respond to lipid antigens presented by CD1d, specifically the glycosphingolipid (GSL) alpha-galactosylceramide (α-Gal-Cer).[62] α-Gal-cer-loaded CD1d has become a useful way to identify and study both human and mouse NKT cells.[63] iNKT cells also respond to a variety of microbial- and host-derived lipids, allowing them to respond to a wide range of pathogens.[64] In addition, iNKT cells respond directly to cytokine stimulation, including IL-12, IL-1β, IL-18, IL-23, and IFN-β.[65,66]

Specific sub-populations of iNKT cells (NKT1, NKT2, and NKT17) have been defined based on the repertoire of cytokines produced. NKT1 cells produce IFN-γ and express the transcription factor T-box 21 (T-bet).[67,68] NKT2 cells produce IL-4, express PLZF,[68] and depend on PLZF, Gata3, and Irf4 for development.[68,69] Finally, NKT17 cells produce IL-17 and express RORγt.[68,70] Lungs are particularly enriched for NKT17 cells, with NKT17 cells located in the lung parenchyma, and NKT1 and NKT2 cells in the marginated vascular pool.[71]

Given the rapidity and potential diversity of their response, iNKT cells play a critical role in the defense against multiple lung pathogens. In bacterial pneumonia, iNKT cells are required for a robust response to infection. Lack of iNKT cells in mice (Jα18–/– mice) results in increased mortality and decreased bacteria clearance in *Streptococcus pneumoniae*,[72] *Pseudomonas aeruginosa*,[73] *Mycobacterium tuberculosis*,[74] and *Chlamydia pneumoniae* models of pneumonia. These studies also show an interaction between iNKT cells, neutrophils, and alveolar macrophages via chemokine (CXCL2) and cytokine (IFNγ) production.[72,73] iNKT cells also play an important role in pulmonary viral infections. Influenza virus–infected DCs stimulate iNKT cells, resulting in rapid production of IL-22.[75] iNKT cells are protective against influenza through modification of the activities of myeloid-derived suppressor cells[76] and proinflammatory monocytes.[77]

Data supporting a role for iNKT cells in chronic inflammation, such as asthma and reactive airways disease, are mixed. Murine studies have shown that mice lacking iNKT cells do not develop airway hyperreactivity in response to OVA treatment.[78] However, germ-free mice demonstrate an accumulation of iNKT in colon and lung and increased morbidity in asthma models.[79] In humans, some studies of iNKT cells in asthmatics show significant alterations in numbers, while other similar studies show no change in iNKT cells.[80–83]

Mucosal-Associated Invariant T (MAIT) Cells Similar to iNKT cells, mucosal-associated invariant T cells (MAIT cells) have a restricted TCR, with humans expressing Vα7.2-Jα33 and Vβ2 or Vβ3,[84–86] while mice express Vα19-Jα33 and Vβ8.1, Vβ8.1, or Vβ6.[87] However, these cells do not respond to CD1d; rather, they are stimulated by the MHC class I–related (MR1) receptor (Table 20-2). This molecule presents riboflavin (vitamin B_2) metabolites,[88,89] which occur in diverse bacterial[90–92] and yeast species.[93,94] In addition, MAIT cells can be stimulated by TCR-independent pathways, including from IL-18.[95,96]

Similar to iNKT cells, MAIT cells develop in the thymus and are regulated by many of the same signaling pathways.[97,98] MAIT cells can also be subdivided by the cytokines that they produce. Thus far, MAIT1 (IFN-γ producing) and MAIT17 (IL-17 and IL-22 producing) have been identified. Unlike iNKT cells, a subset of MAIT cells producing type 2 cytokines has not been identified. MAIT cells display heterogeneity in response to microbes and may function to distinguish between pathogen and commensal.[85,98] Furthermore, MAIT cell numbers are reduced in germ-free mice, in contrast to iNKT cells, which are increased in these mice.[99]

At baseline, MAIT cell numbers in lungs of mice are low. However, cell numbers dramatically expand with infection by intracellular bacteria, including *Salmonella typhimirum*,[100] *Francisella tularensis*,[101] and *Legionella*. MAIT cell number is negatively correlated with disease severity and *P. aeruginosa* infection in cystic fibrosis.[102] Furthermore, studies with MR1$^{-/-}$ mice demonstrate that MAIT cells protect against *E. coli* and *M. abscessus*.[93] In humans, MAIT cells are higher in peripheral blood of patients recovered from than died from severe influenza.[96]

The evidence for MAIT cell involvement in asthma and COPD is limited, but suggestive. In humans, the number of MAIT cells is approximately 5- to 10-fold higher than in mice. In an inner-city asthma study, higher numbers of MAIT cells in circulation at age 1 predicted protection from asthma at age 7.[103] Conversely, lower numbers of MAIT cells in peripheral blood and BAL were associated with more severe asthma.[104] In contrast to the deleterious effects of iNKT cells in mouse models of asthma, these data suggest that MAIT cells may be protective.

Innate Lymphoid Cells

Innate lymphoid cells (ILCs) are defined by a lack of RAG-dependent antigen receptor, an absence of cell-surface markers associated with other lymphoid and myeloid lineages, and a lymphoid morphology.[105] Similar to the other innate-like lymphocytes discussed, parabiosis studies have demonstrated that ILCs are largely tissue resident and do not recirculate.[106] Because these cells do not have antigen receptors, they instead respond to direct stimulus by danger and stress signals. The first of these types of cells to be identified were natural killer (NK) cells and lymphoid tissue inducer (LTi) cells. Additional types of innate lymphoid cells have since been identified and, together with NK and LTi cells, categorized by the constellation of cytokines they produce, namely ILC1 producing type I cytokines (IFN-γ and TNF), ILC2 producing type II cytokines (IL-4, IL-5, IL-9, and IL-13), and ILC3 producing IL-17 and IL-22. The contribution each of these cell types to lung immunity is described further below and in Table 20-2.

Natural Killer Cells (NK) NK cells make up the largest proportion of ILCs in the lungs.[107] They are defined by surface markers CD127$^-$NKp46$^+$Eomes$^+$ and require the transcription factor T-bet.[108] NK cells express a wide variety of activating and inhibitory surface receptors that enable tuning of NK responses based on the combination of binding ligands.[109,110] In the presence of activation signals, NK cells can directly kill target cells (Table 20-2) through the release of perforin and granzyme, recruit additional effector cells by the secretion of cytokines and chemokines, or induce target cell apoptosis through the expression of apoptosis-inducing ligands such as FasL or TRAIL.[110,111] Conversely, NK cells can also produce anti-inflammatory cytokines. In the lung, where over-exuberant action of NK cells could be particularly deleterious, NK cells have a higher proportion of inhibitory to activating receptors, and tightly regulated activation.[112]

ILC1 ILC1s are defined by markers CD90$^+$CD127$^+$RORγt$^-$GATA3^{int}Eomes$^-$NKp46$^+$ and require the transcription factor Tbet.[108] They are very similar in overall surface marker repertoire and function to NK cells, except that they lack direct cytotoxic function (Table 20-2); there are very few ILC1s resident in the lungs of either humans or mice.[108] Although initially thought to be a subset of NK cells, recent lineage data suggest the cells originate from a separate ILC precursor in bone marrow.[105] They respond to stimulation by IL-22 and IL-18, resulting in the production of IFN-γ and GM-CSF.[108]

ILC2 ILC2 are the second most populous ILC in the lungs, after NK cells, and are defined by the markers CD90$^+$CD127$^+$RORγt$^-$GATA3^{hi}.[108] They have been characterized as a "helper-type" ILC (Table 20-2) and function in defense against helminth infection, as well as maintaining barrier integrity in the lung.[110] They are activated in response to IL-1β, prostaglandin D2, IL-22, IL-25, and TLSP and, once activated, upregulate GATA3 to produce IL-5 and IL-13.[108] In the lungs, ILC2 play an important role in lung immunology. Their ability to secrete large quantities of type 2 cytokines gives them an important role in responding to viral and helminth infections, as well as in the pathogenesis of allergic asthma.[113]

ILC3 In general, ILC3 are abundant at mucosal sites but are not commonly found in lungs. They are defined by the markers CD90$^+$CD127$^+$RORγt$^+$GATA3^{int}.[108] They function to promote immunity to extracellular bacteria and fungi (Table 20-2). They respond to IL-1β and IL-23 via the transcription factor RORγt and production of the cytokines IL-17 and IL-22.[110] ILC3 can be further subset based on their production of NKp46(mice) or NKp44 (humans).[105]

Lymphoid Tissue Inducer (LTi) Cells These innate lymphoid cells are similar to ILC3 in that they are dependent on the transcription factor RORγt and produce IL-17 and IL-22 (Table 20-2). However, their main function occurs during fetal development with generation of secondary lymphoid organs, such as lymph nodes and Peyer's patches. Currently, their role in adults is unclear.[110]

LUNG LEUKOCYTES IN THE ADAPTIVE IMMUNE SYSTEM

In addition to the macrophages and innate lymphocytes detailed above, healthy human lungs contain distinct populations of adaptive immunity lymphocytes.[114] While diverse phenotypes are present, a preponderant majority of the T cells from human lungs display surface marker characteristics (most prominently CD69 to inhibit S1P-mediated trafficking) that identify them as resident memory lymphocytes and differentiate them from effector memory, central memory, and other memory lymphocytes.[115,116] In this chapter, we concentrate on resident memory cells (Table 20-3).

Resident memory lymphocytes are functionally defined by their tendency not to re-enter the lymphatics or blood for recirculation, although this may not be insurmountable.[115] Parabiosis experiments in mice demonstrate that lung resident memory lymphocytes are stably retained in the tissue, rather than recirculating with lung-homing propensity; human lung transplant recipients maintain donor resident memory lymphocytes in their lungs without evidence of donor lymphocytes appearing in the blood.[117] Thus, healthy lungs are a niche for a distinct compartment of immunologic memory, which modulates the timing, type, and degree of inflammation in the lungs.

While lungs of human infants contain predominantly naïve and regulatory cells, from later childhood years through adulthood the lungs are stocked with resident memory phenotype lymphocytes.[118–120] Laboratory animals for which pathogen exposures can be carefully controlled reveal that the presence of resident memory lymphocytes is predominantly determined by experiences such as a prior history of infections, rather than age.[24,121] The biology of lung resident memory lymphocytes and their influences on inflammation in the lung are rapidly evolving areas of investigation.

■ Lung Resident Memory CD8$^+$ T Cells

CD8$^+$ resident memory T (T_{RM}) cells are the most studied and best understood of lung resident memory lymphocytes (Table 20-3). CD8$^+$ T_{RM} cells are abundant in adult human lungs, as well as in laboratory mouse lungs that have recovered from respiratory viral infections.[114,118,120–122] They are primarily near conducting airways and pulmonary vasculature (Fig. 20-1), often in clusters but sometimes distributed dispersedly.[123] A subset of CD8$^+$ T_{RM} cells are marked by CD103, which is the αE chain of an integrin that binds E-cadherin on epithelial and other cells. In both mouse and human lungs, CD103$^+$CD8$^+$ T cells are preferentially found among columnar epithelial cells of the airways.[122] CD8$^+$ T_{RM} cells consistently express CD49a, which is the a_1 chain of an integrin that binds to collagens including the collagen IV of basement membranes as well as the type I collagen of connective tissue. CD103$^-$CD49a$^+$CD8$^+$ T cells are found near basement membranes of the airways and in the bronchovascular interstitium, where CD49a facilitates T cell crawling on collagen within tissue.[122] CD49a is essential for retention of CD8$^+$ T_{RM} cells in the lung and for effective memory defense against heterotypic respiratory infection.[122,124]

Lung CD8$^+$ T_{RM} cells arise from a combination of cues. Inflammation to recruit T cells plus local antigen presentation to activate them there can be sufficient to generate CD8$^+$ T_{RM} cells in settings when neither alone can, establishing a satisfying set of rules for their establishment.[125] After severe influenza virus infection, CD8$^+$ T_{RM} cells are present in the lung specifically where injury leads to keratin-5$^+$ epithelial cells that express α_V integrins that activate TGF-β.[126] Unlike in nonpulmonary tissues, formation of CD8$^+$ T_{RM} cells in the lung requires the transcription factor Blimp-1 but not Hobit.[127] Maintenance of CD103$^+$CD8$^+$ T_{RM} cells in the lungs requires Notch signaling in these cells.[128] Antigen specificity of naturally occurring human lung CD8$^+$ T_{RM} cells is only beginning to be detailed. Analyses of T cell receptor (TCR) repertoires reveals limited overlap of lung CD8$^+$ T_{RM} cells with splenic memory CD8$^+$ T cells, suggesting clonal segregation within the tissue likely

TABLE 20-3 Leukocytes of the Adaptive Immune System: Resident Lymphocytes

T cells				
Resident memory CD8$^+$ T cells (CD8$^+$$T_{RM}$)	Variable TcR; CD8$^+$, CD49a$^+$ CD103$^+$ and CD103$^-$ BLIMP-1 dependent	Cytotoxic Suppressor Activated by antigens, cytokines, and neurotransmitters	Direct cytotoxic proteins: granzyme, perforin IFN-γ, TNF-α, PGs	CD103$^+$ in columnar epithelium; CD103$^-$ basement membrane, interstitium
Resident memory CD4$^+$ T cells (CD4$^+$$T_{RM}$)	Variable TcR; CD4$^+$ Multiple other receptors depending on function and TH type Lung residence maintained by IL-7 produced by lymphatic endothelial cells Responsive to antigens, cytokines depending on subset and neurotransmitters	Extensive helper, cytotoxic, proinflammatory, and regulatory functions reviewed in disease specific chapters; memory responses to infections	TH cytokines, cytotoxic proteins, prostaglandins	Airways, interstitium, BALT
B Cells				
Lung-resident memory B cells (B_{RM})	Variable BcR/Ig receptors CD20, CD69, CD27, B220	Ig synthesis, memory responses to infections of II types; helper and suppressor cytokines, antigen presentation	Ig, extensive list of type I and type II cytokines, regulatory factors	Airways, interstitium, iBALT

resulting from locally relevant antigen encounters.[129] Compared to extrapulmonary memory T cells, influenza-reactivity is overrepresented in the lung CD8$^+$ T$_{\text{RM}}$ cells.[123,130,131] Remarkably, the influenza virus antigens recognized by CD8$^+$ T$_{\text{RM}}$ cells include peptide epitopes conserved across influenza A, B, and C viruses,[132] demonstrating that lung-localized lymphocytes can accomplish a previously unanticipated breadth of antiviral defense. Lung CD8$^+$ T$_{\text{RM}}$ cells may be enriched for specificities against many or most respiratory viral pathogens.

In addition to providing cytolytic activity typical of cytotoxic T lymphocytes (CTL), lung CD8$^+$ T$_{\text{RM}}$ cells help direct inflammation in the lungs. By pre-populating the tissue, they do not require time for recruitment like other memory cells do. In addition, CD8$^+$ T$_{\text{RM}}$ cells are in a poised state at rest. They contain more transcripts for cytokines (like IFN-γ and TNF-α) and cytotoxic proteins (like granzyme B) than do memory CD8$^+$ T cells from the blood.[128] These transcripts are not translated to protein until the T$_{\text{RM}}$ cells are activated, but this enables lung CD8$^+$ T$_{\text{RM}}$ cells to secrete their mediators more quickly compared to systemic counterparts.[128,133]

Lung CD8$^+$ T$_{\text{RM}}$ can also rapidly proliferate upon heterotypic lung infection by respiratory viruses,[134,135] amplifying local sources of inflammatory mediators. The daughter progeny of CD103$^+$CD8$^+$ T$_{\text{RM}}$ cells are more prone to being polyfunctional (and simultaneously producing diverse cytokines) than are those from other memory CD8$^+$ cells.[123] The transcriptomes of lung CD8$^+$ T$_{\text{RM}}$ cells reveal that both proinflammatory and anti-inflammatory intermediates are abundant,[128,129] but their net effect seems to be consistently proinflammatory in experimental settings where these cells are selectively depleted or added. A general truism for lungs that contain abundant CD8$^+$ T$_{\text{RM}}$ cells is that their triggering results in more rapid ramping up of inflammation upon infection of the tissues with a heterotypic microbe or an inflammatory stimulus that causes bystander activation. Because speed of the response is so key for defense against microbes in the lungs,[24] these CD8$^+$ T$_{\text{RM}}$ cells often contribute to improved immune resistance in the lung.

Beyond their canonical activation through TCR recognition of antigen, lung CD8$^+$ T$_{\text{RM}}$ cells can also become activated in a bystander fashion, more like the innate lymphocytes detailed above. For example, influenza-elicited lung CD8$^+$ T$_{\text{RM}}$ cells produce IFN-γ after activation by IL-12 secreted by dendritic cells responding to unrelated bacterial stimuli; this amplifies inflammation and improves antibacterial defense in these lungs.[136] The IFN-γ released from influenza-elicited CD8$^+$ T$_{\text{RM}}$ cells after bystander cytokine activation can skew pulmonary inflammation away from Th2 responses and help curb allergic airways disease.[137] Human lung T$_{\text{RM}}$ cells may likely be the CD8$^+$ T cells that respond rapidly to bystander histamine or serotonin with rapid secretion of chemotactic and regulatory cytokines.[138–140] Consequently, lung CD8$^+$ T$_{\text{RM}}$ cells can influence pulmonary inflammation in broad fashion, unrelated to the antigen specificity of the original stimuli that resulted in their establishment.

Lung CD8$^+$ T$_{\text{RM}}$ cells may also contribute to inflammatory pulmonary pathophysiology. To our knowledge, this has yet to be demonstrated in human settings. However, precedent is firmly established with mouse models of incomplete recovery after severe influenza virus infections. Such lungs contain diverse subpopulations of lung CD8$^+$ T$_{\text{RM}}$ cells, one of which (nucleoprotein-specific and PD-1$^{\text{high}}$) receives persistent MHC-I antigen presentation and develops a T cell exhaustion phenotype.[141] Blockade of PD-1 in such mice results in a CD8$^+$ T$_{\text{RM}}$ cell–driven increase in chronic pulmonary inflammation and lung fibrosis.[141] In this same mouse model, aging lungs accumulate increased amounts of CD8$^+$ T$_{\text{RM}}$ cells compared with younger lungs, perhaps via excess pulmonary TGF-β generation.[142] In addition to being overabundant, the older CD8$^+$ T$_{\text{RM}}$ cells are aberrant, clustering distinctly after single cell sequencing, with compromised IFN-γ production and less capability to provide defense against a heterotypic infection.[142] These excessive and aberrant CD8$^+$ T$_{\text{RM}}$ cells contribute to chronic inflammation and diseases, and their depletion is sufficient to reduce fibrosis, monocytes, and neutrophils in the post-influenza lungs.[142] Thus, dysregulated activities of CD8$^+$ T$_{\text{RM}}$ cells may contribute to chronic lung inflammation underlying pulmonary disease.

Lung CD8$^+$ T$_{\text{RM}}$ cells stray from textbook depictions of memory CTL. They do not recirculate through the blood and secondary lymphoid organs, looking for antigen-presenting cells. They can be triggered by a wider than usually envisioned range of stimuli, including antigens that are heterotypic and very broadly conserved, as well as by inflammatory cytokines and neurotransmitters generated by innate immunity. In addition to eliminating infected cells, they are important sources of local cytokines that modulate inflammatory responses in the lung.

■ Lung Resident Memory CD4$^+$ T Cells

CD4$^+$ T$_{\text{RM}}$ cells (Table 20-3) are less well characterized, but more abundant in human lungs, than are CD8$^+$ T$_{\text{RM}}$ cells.[118] Many features of lung CD8$^+$ T$_{\text{RM}}$ cells apply to lung CD4$^+$ T$_{\text{RM}}$ cells.[114] They are tissue-resident, rather than tissue-homing, as demonstrated in parabiosis studies in mice.[143–154] They are found in the interstitial connective tissues near airways and blood vessels[131] (Fig. 20-1). CD4$^+$ T$_{\text{RM}}$ cells derive from effector T cells recruited to the lungs and are maintained there by continuous local production of IL-7, from sources that include lymphatic endothelial cells.[144] Their generation, including IL-7 responsiveness, requires IL-2 receptor signaling to the T cells,[146–148] activated in part by IL-15 produced in the infected lung.[148] They accumulate preferentially in previously infected lung regions.[149] They tend to be polyfunctional, generating multiple cytokines together.[129,149]

CD4$^+$ T$_{\text{RM}}$ cells share transcriptome similarities to CD8$^+$ T$_{\text{RM}}$ cells, and these transcriptome profiles distinguish them from systemic CD4$^+$ memory counterparts found in the spleen.[129] In further similarity to CD8$^+$ T cells and distinct from circulating CD4$^+$ T cells, memory CD4$^+$ T cells in the lungs resemble CTL in their production of perforin and granzymes and their ability to kill infected cells directly.[147] Unlike CD8$^+$ T$_{\text{RM}}$ cells, CD103 is found on CD4$^+$ T$_{\text{RM}}$ cells only rarely. However, the small subset of lung CD4$^+$ T$_{\text{RM}}$ cells that does have CD103 shows similar characteristics to CD8$^+$ T$_{\text{RM}}$ cells, including the absence of Hobit protein, a transcriptional signature reflecting Notch signaling and resting levels of proinflammatory mediators and cytotoxic proteins.[129,150]

CD4$^+$ T$_{\text{RM}}$ cells provide strong protection against respiratory infection. Using adoptive transfer, memory CD4$^+$ T cells from the lungs of mice recovered from influenza infection are far superior to splenic counterparts with identical antigen specificity in conferring defense against subsequent infection.[143] Thus, they are sufficient to provide effective immunologic memory against respiratory pathogens. After recovery from lobar pneumococcal pneumonia, the previously infected lobe has superior protection against subsequent heterotypic pneumococcal infections compared with contralateral lobes, despite the fact that systemic immunity including circulating memory T cells and plasma antibodies should have equal access to all lobes;[149] in this setting, CD4$^+$ T$_{\text{RM}}$ cells localize to the previously infected lobe and their depletion compromises subsequent defense.[149,151] These CD4$^+$ T$_{\text{RM}}$ cells accelerate neutrophil recruitment compared to infections in naïve lungs,[149] which they do by instructing epithelial cells to ramp up production of a neutrophil-attracting chemokine.[151] These data suggest that resident lung CD4$^+$ T$_{\text{RM}}$ cells are essential for effective immunologic memory against respiratory pathogens, and that hastening inflammation in the lungs is a major role of pulmonary CD4$^+$ T$_{\text{RM}}$ cells.

Whether, when, and how $CD4^+$ T_{RM} cells influence pulmonary pathophysiology is only now beginning to be considered. In mouse models of house dust mite allergy-driven airways disease, both circulating and resident $CD4^+$ T cells contribute to inflammation and sequelae, but distinctly.[145,146,152] While circulating cells amplify the perivascular recruitment of eosinophils and T cells, the lung $CD4^+$ T_{RM} cells are responsible for the mucus metaplasia, airway hyperresponsiveness, and activation of recruited eosinophils.[145,146,152] $CD4^+$ T_{RM} cells are also induced and responsible for airway hyperreactivity in a more reductionist model involving ovalbumin (OVA)-induced allergic responses in the lung.[153] These data implicate $CD4^+$ T_{RM} cells in driving the deleterious pulmonary inflammation in asthmatic airways. $CD4^+$ T_{RM} cells may be involved in the pulmonary inflammation of additional lung diseases, but further studies are needed.

Again, resident memory T cells stray from textbook depictions. Lung $CD4^+$ T_{RM} cells do not recirculate through the blood and secondary lymphoid organs, looking for antigen-presenting cells. Instead, they reside in the lungs and influence local immunity. They are capable of being cytotoxic T cells that eliminate infected cells, and they are important sources of local cytokines that modulate inflammatory responses in the lung.

■ Lung-Resident Memory B Cells

The concept of lung-resident memory B (B_{RM}) cells has been established recently,[154] based largely on studies of mice recovering from influenza infection. The lungs of such mice contain increased numbers of memory B cells.[155–157] These cells are in extravascular compartments;[157,158] they express the CD69 marker that distinguishes T_{RM} cells from other resting T cells;[157–159] and they do not recirculate based on parabiosis studies.[157] Upon adoptive transfer to naïve mice, memory B cells from the lung provide superior protection compared with their counterparts from the spleen.[159] Lung memory B cells produce multiple isotypes of antibodies against influenza when stimulated;[156,157] the lung, in particular, harbors memory B cells with immunoglobulin B cell receptors capable of recognizing heterotypic strains of influenza.[158] In concert, these data support the concept that, like T_{RM} cells, B_{RM} cells populate lung tissues after recovery from pulmonary challenge and improve protection against respiratory infection (Table 20-3).

While mouse models of recovery from influenza infection are instructive, they involve persistent pulmonary pathology that includes bronchus-associated lymphoid tissue (BALT) and dysplastic epithelial structures.[160,161] B_{RM} cells also arise in lungs of mice that recovered from pneumococcal pneumonia, displaying neither BALT nor dysplastic epithelium.[162] These lung B_{RM} cells are in the loose connective tissue of bronchovascular bundles (Fig. 20-1), often near $CD4^+$ T_{RM} cells.[162] They produce antibodies against heterotypic strains of pneumococcus.[162] In addition to CD69, they are characterized by surface expression of PD-L2, CD73, and/or CD80, and depletion of $PD\text{-}L2^+$ B cells from the lungs renders recovered mice more susceptible to pneumonia caused by heterotypic pneumococci.[162] Collectively, these data suggest that B_{RM} cells in histologically normal lungs are essential for optimal protection against heterotypic respiratory infection.

Healthy human lungs contain B cells, but they are far less abundant than T cells.[118] Memory ($CD27^+$) B cells in human lungs have CD69, but not CD38 or CD83 on their surface,[162] suggesting that they are resident rather than recently activated memory B cells. Memory B cells recognizing influenza virus are found in the lungs (as well as secondary lymphoid organs) and have an increased presence compared with peripheral blood.[163] The specificities and functions of lung B_{RM} cells, including their contributions to immunologic memory and to inflammation in the lungs, are still largely unknown and constitute important knowledge gaps requiring further investigation.

LUNG TERTIARY LYMPHOID STRUCTURES

When exposures are chronic or fail to resolve, immunologic remodeling becomes more pronounced[164–166] and can result in organized aggregates of lymphocytes, variously called *bronchus-associated lymphoid tissue* or BALT (Fig. 20-1), inducible BALT (iBALT), tertiary lymphoid organs (TLO), or tertiary lymphoid structures (TLS). Defining features for such organized structures are the clustering of T cells and of B cells into anatomically segregated, but adjacent, areas and the presence of high endothelial venules expressing peripheral node addressin (PNAd). Additional distinguishing features are the presence of fibroblastic reticular cells and follicular dendritic cells, as well as evidence of B cell germinal center reactions, class switching, and activation-induced cytidine deaminase (AID) expression for somatic hypermutation. True BALT includes all the above components, recapitulating elements of secondary lymphoid organs within the tissue of the lung. Such organized structures are observed in smokers and patients with pulmonary disease but are atypical for healthy lungs.[164–166]

Although often portrayed as a dichotomy between healthy, BALT-free and diseased BALT-containing states, the ways in which adaptive immunity lymphocytes accumulate and interact in healthy lungs may more accurately reflect a continuum between these extremes. While the naïve lungs of infants contain in effect no immunologic memory,[119] and while fully formed BALT establishes an aberrant new lymphoid organ within the lung,[164–166] the T_{RM} cells and B_{RM} cells described above are characteristic of normal lung tissue.[114,118,120,162,163] These lymphocytes likely interact with each other and with other immune and stromal cells of the lung, even when organized anatomic structures are imperceptible.[167]

Immune cell organization may be dynamic and context dependent. Biological pathways upstream and downstream of BALT[164–166] may apply to normal, healthy lungs, and the T_{RM} cells and B_{RM} cells of normal, healthy lungs may be predecessors or remnants of more organized lymphoid structures. There is two-way communication between pulmonary inflammation and these aggregates of lymphocytes with varying degrees of organization. Regardless of how organized, lymphocyte clusters and their interactions provide an immunologic "tone" to the lower respiratory tract. The importance of BALT in immunologic tone has become more evident in the era of lung transplantation. Donor lungs have greater survival if they contain BALT with abundant regulatory T cells which appears dependent upon IL-22.[168–170] These results, combined with observations of BALT governing lung immune activities during acute respiratory infections and chronic pulmonary diseases,[164–166] reveal that lung TLOs have myriad and profound effects influencing integrated immune responses within the lower respiratory tract.

CHAPTER 21

Mast Cells and Eosinophils

Edward S. Schulman
Peter H.S. Sporn
Amali E. Samarasinghe

INTRODUCTION

Hematopoietic stem cells that differentiate into common myeloid stem cells give rise to granulocytes that include mast cells (MC), eosinophils, basophils, and neutrophils. In addition to the shared heritage, granulocytes share physical and functional similarities. MCs and eosinophils are popularly known for their presence and function during allergic diseases. Because physicians have noted a clear connection between mast cell activation and the subsequent appearance of eosinophils both within the circulation and in tissues for over a century, MCs and eosinophils are considered together in this chapter.

Both cell types were discovered in the 1870s by the same observer, Paul Ehrlich, who noted that some cells stained in a peculiar fashion when incubated with standard aniline dyes such as toluidine blue and alcian blue. He used the term *metachromasie* or metachromasia to describe the peculiar color modifications that occurred and the term *Mastzellen*, meaning "well fed" or "fattened" in German, to describe what we now call MC. Interestingly, this latter term is now known to be a misnomer, since MC cytoplasmic granules are not phagocytized but rather synthesized during cell growth and again during regranulation. Ehrlich also noted that some cells stained intensely when incubated with the acidic dye eosin. As a result, these cells were called *eosinophils* to mean "eosin lovers." Both cell types have been evolutionarily conserved (albeit with some differences among species), underscoring their importance to the immune system. Studies of these two cell types, over the ensuing years, have provided great insight into their roles in biology both in health and in disease.

MAST CELLS

The capacity of strategically localized MCs to rapidly release an assortment of powerful chemical mediators makes this cell a unique member of the body's immune response network. Although most frequently discussed in the context of hypersensitivity immune responses, MCs are also known to participate in normal physiologic processes including gastric acid secretion,[1] angiogenesis,[2,3] lipid clearance,[4–8] and host defense.[9,10] MCs also participate in nonallergic pathophysiologic processes such as inflammatory bowel disease,[11,12] arthritis,[13] scleroderma,[14,15] tumors, interstitial pulmonary fibrosis,[16–19] envenomation,[3,20–23] and atherosclerosis.[4,5,24,25] Over the years, basophils have been confused with MC in a number of contexts.[26] This confusion is due, in part, to a number of similarities between the cells, including the shared expression of FcεRI (high-affinity receptor for Fc fragment of immunoglobulin E, IgE), release of preformed histamine, and metachromatic staining. However, MCs are mononuclear cells and are almost exclusively localized to tissues. In contrast, basophils are circulating polymorphonuclear cells that are found occasionally in tissue reactions, including the late-phase allergic response. In addition, significant differences in these two cell populations exist in their cell lineage, ultrastructure, mediator release biochemistry, mediator profiles, pharmacology, and surface antigenicity.

Origins of Mast Cells

MCs are believed to be derived from pluripotent hematopoietic stem cells.[27–29] Tryptase-negative MC colony–forming cells leave the bone marrow and circulate with a surface phenotype that is Lineage$^-$, CD (cluster of differentiation) 34$^+$, c-kit (CD117)$^+$, CD13$^+$, CD135$^+$, CD45RA$^-$, and CD14$^-$.[30] MC progenitors express the α4β1 integrin (VLA-4), which regulates adhesion to activated endothelial cells.[31] The agranular mononuclear monocyte progenitors home in a tissue-specific manner where they complete differentiation, maturation, and synthesis of granule proteases in response to microenvironmental factors, including the matrix and chemokines from fibroblasts, endothelial cells, airway smooth muscle cells, and possibly T cells. Lung inflammation-induced recruitment of progenitors requires both α4β7 and α4β1.[27] The microenvironmental factor most critical in chemotaxis, differentiation, adhesion, proliferation, maturation, and survival is stem cell factor (SCF) which is the ligand for c-kit tyrosine kinase receptor. This receptor is expressed on the MC surface throughout its life span.[32,33]

Morphology

All MCs are round/elongated mononuclear cells ranging from 8 to 20 μm in size with heterogeneous cytoplasmic granules (Fig. 21-1).[34,35] Cell membranes are outlined by short, narrow surface folds.[36–39] A variety of granule-filling patterns that can be affected by cross-sectioning occur within individual cells: scrolls, crystals, particles (the least seen in pure form), and combinations (mixed). Each MC may contain up to 1000 secretory granules that range from 200 to 800 nm in diameter and outlined by a perigranular membrane.[40]

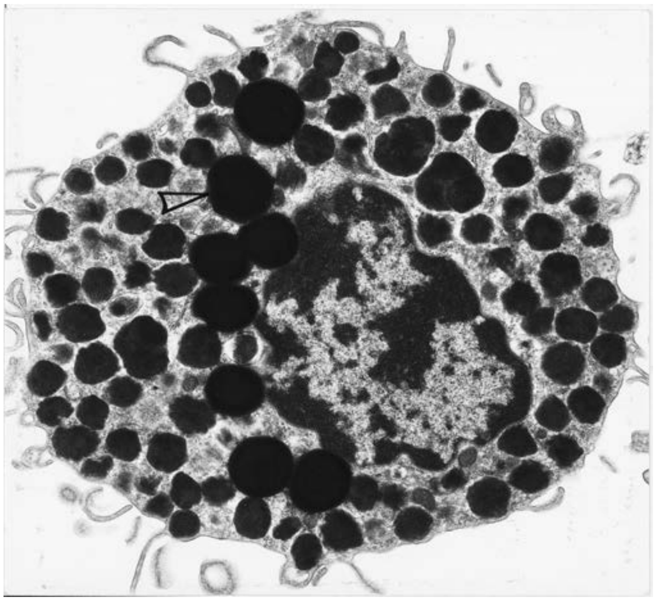

Figure 21-1 Ultrastructure of the human lung mast cell after purification. The mast cell is a mononuclear cell packed with multiple dense cytoplasmic granules that vary in size and shape. Eight electron-dense lipid bodies *(open arrow)* are bunched near the nucleus (×15,000). *(Reproduced with permission from Galli SJ, Austen KF: Mast Cell and Basophil Differentiation and Function in Health and Disease. New York, NY: Raven; 1989.)*

Mast Cell Heterogeneity

Striking differences in the morphology, T cell dependence, resident proteoglycans, and responsiveness to secretagogues and drugs have been described in human MC.[34,41–47] The ontogeny of this heterogeneity, as well as the differing roles these MC play in physiology and disease remain speculative.

The most common classification of human MC is based on the expression of protease profiles as determined by immunohistochemical staining using monoclonal antibodies. According to this system, the serine proteinase tryptase (T) is expressed in virtually all human MC, and a subset, predominantly in the submucosa of the gut and in the skin and within asthmatic airway smooth muscle also express chymase (C) and multiple other proteases including carboxypeptidase A3 (CPA3) and cathepsin G. Mast cells that express tryptase alone are classified as the MCT type, and those with additional proteases as the MCTC type.[48–50] Because significant numbers of both types can be found in the same organ (e.g., lung), tissue location cannot dictate the protease type. In the lung, only 8% to 35% of MCs are MCTC, 1% is MCC, and the remainder are MCT. The protease system does follow some rules of distribution and function. MCT are preferentially localized in bronchi, bronchioles, mucosal surfaces, alveolar parenchyma, lamina propria, and areas of T cell infiltration, and they are reduced in immunodeficiency syndromes. The MCTC phenotype does not appear immune related and is more prevalent in pulmonary vessels and pleura. As detected by immunohistochemical staining, the MCTC subtype more selectively expresses interleukin 4 (IL-4) (85% MCTC vs. 15% MCT). IL-5 and IL-6 are almost exclusively restricted to the MCT subtype. Within human lung, different compartments appear to show site-specific expression of FcεRIα, IL-9 receptor, histidine decarboxylase (higher in MCT of bronchi than MCT of alveoli), 5-lipoxygenase, leukotriene (LT)C$_4$ synthase, vascular endothelial growth factor (VEGF), basic fibroblast growth factor (FGF),[51] and renin.

Human lung mast cell (HLMC) diameters vary between 8 and 18 μm with the majority being 12 to 15 μm. Histamine contents of 2.5 to 10.0 pg/MC vary directly with cell diameter. HLMC densities vary from 1.053 to 1.123 g/mL with the majority (67%) between 1.077 g/mL and 1.088 g/mL These diameter- and density-based subtypes also are distinct with respect to mediator content and function. MC location also subserves function: airway and parenchymal MC differ in their granule secretion. Finally, at least two types of proteoglycans are present in HLMC: chondroitin sulfates, predominantly chondroitin sulfate E, and heparin. HLMCs are both positive and negative for the heparin-sensitive dye berberine sulfate, whereas stomach MCs synthesize exclusively chondroitin sulfate E and not heparin.[52,53]

Anatomic Localization

MCs are present in all organs but are particularly abundant in the nose, skin, gastrointestinal tract, and lung. They reside primarily near blood vessels, within the adventitia of arteries, and near lymph vessels and nerves.[54–56] HLMC are estimated to range from 500 to 4000 per mm^3 of tissue. In non-asthmatics, HLMCs localize to submucosal connective tissues and not epithelium or smooth muscle. Although data in asthmatics are conflicting as to whether the numbers MCs are increased versus non-asthmatics, MCs localize to three critical sites: bronchial epithelium,[57] airway mucus glands,[58] and within smooth muscle.[59–62] Mediator release from the small numbers of HLMCs within the epithelium may subserve initial antigen recognition and also be strategically placed to respond to nonantigenic signals, including hyperosmolarity,[63] as well as "endogenous" mediators, including extracellular adenosine and adenosine 5′ triphosphate (ATP).[64–66] In the case of aeroallergens, permeabilization resulting from epithelial MC mediators enhances further antigen penetration to deeper airway smooth muscles and mucus glands, which in turn, promotes bronchoconstriction and mucus secretion, respectively. The finding of HLMC within the smooth muscle layer appears to be a common and critical finding in asthmatics. It is an uncommon finding in non-asthmatics and in patients with eosinophilic bronchitis. Other than MC localization to alveolar smooth muscle, the latter condition has virtually identical structural remodeling changes to asthma but is not associated with obstruction or airway hyperresponsiveness (AHR).[59,67] In the lung periphery, abundant MCs reside within small airways and in the alveolar septa, within a few microns of the alveolar lumen.[65] The small numbers of MC in bronchoalveolar lavage (BAL) fluid (≤0.1% of all cells) likely result from epithelial shedding.[55,68]

Perivascular MC are also important in the initiation and unfolding of lung hypersensitivity responses. Recently, a novel mode of antigen delivery to pulmonary perivascular MC has been described. Intravascular projections from perivascular dendritic cells continuously sample blood for antigens. Dendritic cells then rapidly feed antigen-bearing microvesicles to neighboring immune cells including mast cells.[69]

Activation

Immunologic allergic activation of MC is the mechanism most studied.[70] It results from allergen cross-linking of allergen-specific cell surface IgE molecules and subsequent aggregation of IgE-high-affinity receptors (FcεRI) to which they are attached.[71,72] Receptor dimerization is the minimum cross-linkage requirement for initiation of IgE-mediated activation. In vitro, immunologic MC activation can be achieved using animal-derived or monoclonal antibodies directed against human IgE or the FcεRI-receptor itself. The mechanism(s) involved in chronic HLMC activation characteristic of asthma are not known but likely reflect low-level allergen activation. Monomeric IgE alone, in the absence of antigen, has been reported to induce prolonged mediator release, a mechanism that may be operative within the asthmatic airway.[73] Many mast cell-related reactions are triggered by non-IgE mechanisms. These reactions have been termed "pseudo-allergic" reactions or "nonallergic anaphylaxis."[74] These triggers include opioid drugs, calcium ionophores, hyperosmolar stimuli, "histamine-releasing activities" derived from human alveolar macrophages and other cells,[75–78] basic compounds (e.g., 48/80), neuropeptides (e.g., substance P and hemokinin-1), and cationic ligands including many U.S. Food and Drug Administration (FDA)-approved drugs (e.g., atracurium, ciprofloxacin) (reviewed by Thapaliya et al.[79]). In general, the profile of agents that degranulate MC from human intestine and synovium is similar to that of HLMC but different from skin MC. Even within lung compartments, responsiveness to triggers may vary. Compound 48/80 is reported to degranulate BAL MC, whereas those from lung parenchyma are minimally responsive. Bee venom phospholipase (PLA)2 and antigens from dust mites, cockroaches, pollens, and fungal spores contain phospholipases and proteases, which can lead to MC release through the protease-activated receptor (PAR) 2.[80,81]

The MC receptor responsible for mediating effects of compound 48/80, substance P, hemokinin 1, and cationic drugs recently was identified as MRGPRX2 (MAS-related G protein–coupled receptor X2) in humans and the mouse ortholog as MRGPRB2.[82] Human dermal mast cells have markedly higher transcript levels of MRGPRX2 than HLMC, which explains the relative in vitro unresponsiveness of HLMC to 48/80 and neuropeptides.[83,84] However, HLMC upregulation of MRGPRX2 has been reported in asthma-related deaths vs. non-asthma related deaths.[85] Neutrophil cathelicidin (LL-37), eosinophil major basic protein, and peroxidase and epithelial β-defensins, all implicated in asthma, activate human MC via MRGPRX2. The purified anaphylatoxin C5a, an active trigger of human basophils and dermal MC, is generally inactive in HLMC,[86,87] although CD88, the receptor for C5, has been reported in the MCTC.[88]

IgG/antigen immune complexes via FcγR can trigger MC-induced anaphylaxis in high-dose antigen reactions (e.g., intravenous administration of drug). The immune complexes can also act by blocking low-dose antigen access to IgE and interacting with the inhibitory receptor FcγRIIB. Thus, this dual role IgG can play is dependent on antibody and antigen concentrations.[89]

In both mouse MC and human progenitor–derived MC, several innate pathogen-associated molecular pattern recognition receptors (PAMPs), including Toll-like receptors (TLRs), have been reported. TLR-2 and -4 have been reported in HLMC.[90–92] The expression of TLR and effects on activation of HLMC remain poorly defined. Human peripheral blood–derived cultured MCs are reported to express TLR-1, TLR-2, TLR-4, TLR-5, TLR-6, TLR-7 and TLR-9. They also produce type I IFNs following exposure to double-stranded RNA and or virus, the former confirming functional TLR-3 expression.[90]

Finally, the immunoglobulin superantigens protein A of *Staphylococcus aureus* and protein L of *Peptostreptococcus magnus* can directly induce HLMC mediator release.[93] The superantigens bind to the variable regions of either the heavy (V_H3) or light chain (κ) of IgE. Angiogenic (VEGF-A) and lymphangiogenic (VEGF-C) factors also were rapidly in 30 minutes released along with histamine, a response enhanced after prolonged (12 hour) HLMC preincubation in IL-33.[93]

Modulators of Activation

Although not acting as direct release triggers, several endogenous chemicals in the MC microenvironment and/or their receptors can influence activation. Extracellular adenosine triphosphate (ATP) and its breakdown product, adenosine, are potent modulators of HLMC degranulation, although neither directly activates HLMC degranulation in vitro.[64–66,94,95] Adenosine exhibits a bimodal effect on IgE-mediated HLMC challenge: enhancing histamine release at 10^{-6} to 10^{-4} M and inhibiting release at 10^{-3} M. ATP (10^{-4} M), at local concentrations achievable in vivo, consistently enhanced anti-IgE–induced histamine release. The adenine nucleotides consistently enhanced anti-IgE–induced histamine release; the rank order for this action was ATP > 2mSATP (2-methyl-thio-ATP) >α,βmATP (α,βmethylene-ATP) >β,γmATP (β,γmethylene-ATP), suggesting mediation by a P2Y-purinoceptor subtype. P2X7, strongly expressed on the HMC-1 cell line and mouse mast cell models, is not expressed in freshly isolated and purified HLMC. In asthmatics, aerosolized adenosine induces bronchoconstriction, an effect not observed in other groups of pulmonary patients or normals.[96] The ability of antihistamines to inhibit this response has directly implicated activation of allergically primed airway MC by adenosine.[97,98] Components of the local connective tissue matrix such as fibronectin also modulate MC reactivity.[99]

Airway challenge with allergens, viruses, and irritants can trigger release of epithelial alarmins such as IL-33, IL-25, and thymic stromal lymphopoietin (TSLP).[100] IL-33 primarily binds to the IL-1 receptor family member ST2. IL-33/ST2 complex assembles with the IL-1 receptor accessory protein (IL-1RAcP), which is needed for signal transduction. ST2 is highly expressed on Th2 cells and group 2 innate lymphocytes. In lung samples from patients with severe asthma, IL-33 expression was higher than in those with mild asthma. Peripheral blood CD34+ precursor-derived mast cells and HLMCs pretreated with IL-33 showed enhanced degranulation responses.[93,101] HLMCs robustly express ST2 both intracellularly and on their surface. Expression is markedly enhanced within 2 hours of IgE-mediated stimulation. In a purified HLMC microarray analysis, ST2 is the fourth most expressed cytokine-related gene only preceded by granulocyte macrophage-colony stimulating factor (GM-CSF), IL-8, and IL-3.[102] It should be noted that these most abundantly expressed HLMC cytokines (GM-CSF and IL-3) appear to be vital to create an asthmatic milieu in a “next-generation” humanized mouse model, IL-3/GM-CSF or IL-3/GM-CSF/IL-5 transgenic (Tg) NOD/Shi-*scid*-IL2rγ^{null}(NOG) mouse. This GM-CSF/IL-3 milieu produces a human type-2 allergic immune response in which human myeloid cells including mast cells, basophils, and eosinophils differentiate and maturate.[103]

In human peripheral blood– or cord blood–derived MC, TSLP alone does not trigger degranulation, but in combination with IL-1β or TNF-α it releases several cytokines and chemokines.[104,105] Human lung biopsies demonstrate expression of TSLP in bronchial and submucosal mast cells. Asthmatic airways have a higher percentage of MCs expressing TSLP compared to non-asthmatic controls. Both airway smooth muscle and mast cells embedded within express TSLPR.[106]

Human bone marrow–derived MC produce IL-25 following IgE-mediated stimulation.[107] HLMC express IL-25 mRNA transcripts constitutively and levels increase within 2 hours of IgE-mediated stimulation.[102]

Although most research in MC has been performed on receptors that mediate activation, MC responses can involve cross talk with inhibitory signals. A number of the MC inhibitory receptors contain **i**mmunoregulatory **t**yrosine **i**nhibition **m**otifs (ITIMs). Following inhibitory receptor activation, these regions are phosphorylated and then recruit phosphatases that dephosphorylate key signaling molecules.[108] ITIM-containing MC inhibitory receptors include platelet-endothelial cell adhesion molecule 1 (PECAM-1,CD31), Fc-gamma-RIIb,[89] CD300a,[109] the c-lectin mast cell function–associated antigen (MAFA),[110] and sialic acid–binding immunoglobulin-like lectins (Siglecs). The latter are expressed on MC and eosinophils (see “Eosinophils,” below).[111] HLMCs express mRNA for Siclec-6 but not Siglec-8.

Biochemical Analysis of HLMC Activation

Elegant studies defining the biochemical events following IgE-mediated activation have been performed in rodent MCs or cell lines.[112,113] Evaluations of similarities and differences in HLMC activation await future investigations. Two receptors for IgE have been identified. The FcεRI on MC and basophils is expressed in a tetrameric form (αβγ2). On platelets, neutrophils, monocytes, eosinophils, smooth muscle, and antigen-presenting cells the IgE receptor is present in a trimeric form (αγ2). The Fc fragment of IgE binds to the α-chain of FcεRI. Expression of the β-chain amplifies signaling. A low-affinity IgE receptor (FcεRII; CD23) is present on B cells but not on MC or basophils.[114] Serum IgE levels correlate with basophil expression of FcεRI, likely indicating a role for IgE in stabilizing the FcεRI on the cell surface. As noted earlier, receptor dimerization is the minimum cross-linkage requirement for antigen-mediated allergen activation through the FcεRI. Following receptor aggregation, multiple signal transduction pathways are activated. Since FcεRI possesses no inherent tyrosine kinase activity, critical to the sequential activation are two tyrosine kinases: Lyn, which is associated with the β chain, and Syk. Lyn binds to the β-chain–associated immunoreceptor tyrosine-based activation motifs (ITAMs), which are phosphorylated after FcεRI aggregation. For degranulation to proceed, Syk then binds to the γ-chain–linked ITAMs, which are also phosphorylated after receptor aggregation. The Lyn:Syk-driven pathway directly or indirectly stimulates tyrosine phosphorylation of several adapter proteins, including the transmembrane adaptor molecule linker for activation of T cells (LAT) among others. These events lead to the generation of inositol triphosphate (IP3), which induces Ca^{2+} mobilization from intracellular rough endoplasmic reticulum stores. Phospholipase C-γ1 and PLC-γ2 are also activated.[115–123] In this context, at 2 min following FcεRI aggregation, extracellular calcium influx occurs through CRACM channels (Ca^{2+} release–activated Ca^{2+} [CRAC] modulator 1),[124,125] which is a prerequisite for degranulation to proceed over the next 5 to 20 min. Other “early-phase” granule-associated and lipid mediators (e.g., arachidonate metabolites) also are released over 20 min. Over the ensuing 1 to 24 h, mRNAs for select cytokines are generated followed by their protein synthesis and release.

Morphology of Degranulation and Regranulation

Following IgE-mediated (anaphylactic) activation of HLMC, granules swell and their perigranular membranes fuse to form canaliculi that open through multiple pores to the cell exterior. Within 20 minutes of activation, granular matrix materials solubilize within these intracytoplasmic channels and empty. In HLMC, only rarely is extrusion of non-solubilized granules observed. Lipid bodies (LBs), which are electron-dense non-membrane-bound organelles,[126–129] remain adjacent to these channels. They appear to serve as repositories of arachidonic acid and occasionally release lipid into the degranulation channels. In vivo, a process termed *piecemeal degranulation* (PMD) is more frequently observed than anaphylactic degranulation.[130] This process involves the budding of small vesicles from granule membranes and their movement to the cell surface. PMD may be more typical of the ongoing MC release observed in chronic asthma.

Depending on the extent to which an individual cell has degranulated, one of two predominant types of regranulation are observed individually or in combination. In partially degranulated cells, the channel (formerly perigranular) membranes are reutilized, and regranulation events resemble degranulation in reverse. In cells with more complete degranulation, the channel membranes are placed in continuity with the plasma membrane and externalized. This results in the appearance of elongated, activated cell surface folds. These excessive folds can be internalized or shed. Shedding results in cells that are initially small (7 μm) but then enter a rapidly expanding recovery cycle to produce a fully mature cell.

Chemical Mediators

The clinical expression of MC-mediated responses may reflect the individual mediators or, in certain instances, the interplay of the multiple mediators these cells release (Table 21-1). The temporal sequence of their release appears critical to the development of both the early- and late-phase responses after antigen challenge (Fig. 21-2). Certain mediators are virtually unique to MC (e.g., tryptase, chymase, heparin), and others are shared with one or more other cells (e.g., histamine, LTC_4, and IL-5).

Mediators released within minutes after activation are divided into preformed, or secretory, granule-associated mediators (e.g., histamine) and non-preformed, or newly synthesized mediators (e.g., lipids). It is now known that tumor necrosis factor alpha (TNF-α) may be both preformed and newly synthesized. Other cytokine mediators, including IL-5 and IL-13, are detected over hours and may be critical to the evolution of the "late-phase" response.

Preformed Mediators

Below we discuss a number of preformed mediators, including histamine, proteoglycans, chemotactic factors, and proteases.

Histamine

Histamine is produced by several cell types that express the enzyme histidine decarboxylase that synthesizes histamine from histidine. The cells that can secrete histamine but cannot store it include neutrophils, macrophages, monocytes, and keratinocytes. MCs and basophils can both store and secrete histamine.

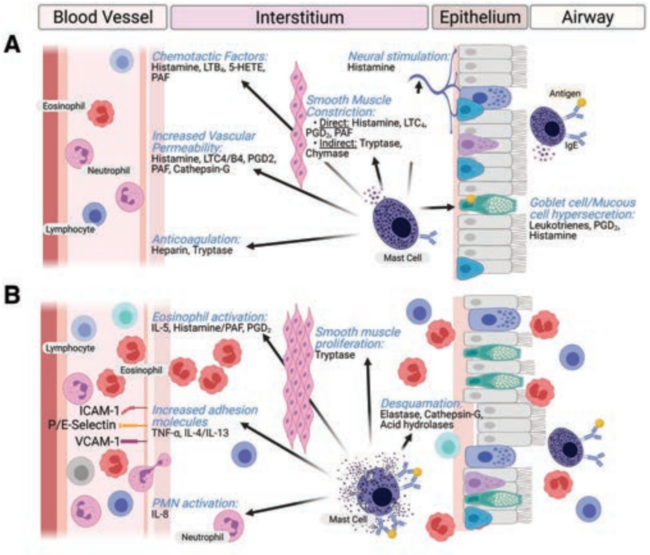
Histamine measurements have served as a classic marker of MC-mediated events. The pleiotropic effects of histamine are mediated through the differential expression, regulation, and distinct intracellular signals evoked by four distinct receptors, H1, H2, H3, and H4. Only the H4 receptor has been reported to be both expressed and functional (chemotaxis) in HLMC.[131] The actual role of histamine in asthma remains less clear, although levels in BAL fluid are many-fold higher in asthmatics and plasma levels rise three- to five-fold following airway antigen challenge. Most histamine-induced allergic respiratory reactions are mediated via the H1 histamine receptor subclass, producing enhancement of vascular permeability, mucus production, initiation of neurogenic reflexes, and bronchial smooth muscle contraction. The reasons for the marginal value of the H1 receptor–blocking drugs in asthma may be due to high local tissue concentrations of histamine that exceed the inhibitory capacity of these agents and/or the redundancy of histamine actions with the multiple other mediators that are released.

TABLE 21-1 Human Mast Cell and Eosinophil Mediators

	Mast Cells	Eosinophils
Granule-associated (preformed) mediators	Histamine	MBP
	Heparin	ECP
	Chondroitin-sulfate E	EDN
	TNF-α	EPO
		CLC protein
Enzymes	Tryptase	EPO
	Chymase	ECP, EDN
	Cathepsin G	Collagenase
	Elastase	MMP-9
	Carboxypeptidase-A	Indoleamine 2,3-dioxygenase
Acid hydrolases	β-hexosaminidase	β-glucuronidase
	β-glucuronidase	Arylsulfatase B
	Arylsulfatase	
Lipid mediators (non-preformed)	PGD_2	LTC_4
	LTC_4	15-HETE
	LTB_4	5-oxo-ETE
	PAF	PAF
	Thromboxane-A_2	
Cytokines	IL-4, IL-5, IL-13	IL-1α, IL-2, IL-3
	IL-6, IL-8	IL-4, IL-5, IL-6, IL-8
	TNF-α	IL-10, IL-12, IL-13
	TGF-β	IL-16, IL-17
	bFGF	GM-CSF
		TNF-α
		TGF-α
		TGF-β
		SCF
		NGF
		PDGF
		VEGF
Chemokines		CCL3
		CCL5
		CCL13
		CCL11
Reactive oxygen products	None detected	$O_2\bullet^-$, H_2O_2, OH HOBr, HOCl

Proteoglycans

MC proteoglycans serve as the major determinant for the metachromatic tinctorial properties of the cell and form the granule backbone to which other preformed mediators, including histamine and neutral proteases, are bound. HLMCs synthesize heparin



Blood Vessel
Interstitium
Epithelium
Airway
A
Chemotactic Factors:
Histamine, LTB$_4$, 5-HETE, PAF
Neural stimulation:
Histamine
Eosinophil
Smooth Muscle Constriction:

Neutrophil

Figure 21-2 Effects of mast cell mediators in the early- and late-phase responses following airway allergen challenge. **A.** Early phase: Mediators are released within minutes following antigen cross-linking of allergen-specific IgE on the cell surface. Mechanisms of the initial airflow obstruction that persists for 30 to 60 minutes include smooth muscle constriction, edema formation due to increased vascular permeability, nerve stimulation, and mucus hypersecretion from both goblet cells and submucosal glands. **B.** Late phase. Within hours, the effects of newly synthesized and released cytokine mediators along with delayed effects of early-phase mediators produce recurrent airway obstruction. Mast cell mediators and cytokines can increase the expression of adhesion molecules on endothelial cells, both recruit and activate leukocytes (particularly eosinophils), contribute to epithelial desquamation, and stimulate smooth muscle proliferation.

and chondroitin sulfate E proteoglycans in roughly a 2:1 ratio.[52] In humans, heparin appears to be unique to MC. In addition to anticoagulant activity, heparin possesses both anti-inflammatory and immunoregulatory properties.[132–134] Heparin may limit allergic responses in the skin, nose, and lung and exert protective effects on exercise-induced asthma (EIA). The inhibitory effects may be related to the extracellular binding and inhibition of multiple mediators, including histamine and cytokines.

Chemotactic Factors

Within hours of MC activation, airway inflammation (the late-phase response) at the tissue level is characterized by the infiltration of leukocytes. This response is principally eosinophilic but also contains neutrophils and, over time, lymphocytes. Chemotactic mediators may be derived directly from MC and/or other cells through secondary stimulation. Early-phase MC-derived eosinophilic chemotactic activities include LTB$_4$, platelet-activating factor (PAF), and histamine.[135] HLMCs robustly express CXCL8 (also known as IL-8), which along with LTB4, attracts neutrophils. MCs are responsive to chemokines released from other cells. Airway smooth muscle secretes a number of chemotactic factors including CXCL-8, CXCL-10 (also known as interferon gamma–induced protein, IP-10), CXCL-11 (also called interferon-inducible T cell alpha chemoattractant, I-TAC), and CXCL-12 (also known as stromal cell–derived factor 1, SDF1). It appears that the CXCR3/CXCL10 axis predominantly mediates the HLMC migration into the airway smooth muscle observed in asthmatic airways.[136,137]

Proteases

Large quantities of neutral proteases are contained within MC and constitute the predominant protein component of the secretory granule. The proteases include tryptase, chymase, cathepsin G, carboxypeptidase A3, and elastase.[48–50,138]

Tryptase is the predominant neutral protease of the MC granule. Within the MC granule, tryptase is a tetramer that is stabilized by its association with heparin proteoglycan. The concentration of tryptase in pulmonary MC is 11 pg per MC. Since the concentration of tryptase in circulating basophils is more than 100 times lower than in MCs, responses characterized by the presence of histamine but not tryptase at a reaction site or in the circulation implicate mediation by basophils and not MC.

Two genes produce tryptase: *TPSAB1*, which can encode alpha (α)- and beta (β)-protryptase; and *TPSB2,* which encodes only β-protryptase. All humans appear to produce β-protryptase; α-protryptase is lacking especially in those of Asian (10%), European (23%), or African (41%) ancestry.[139] The amount of protryptase protein expression can vary dependent on the number of gene copies of each (e.g., 1 to 5 copies). Further, their ratios can result in an α- vs. β-tryptase “dosage effect.” This ratio can have clinical consequences.[140,141] Resting MCs continuously, spontaneously, and without activation release large portions of synthesized α- and β-protryptases into the circulation. Therefore, the basal “total” tryptase level from a blood draw is genetically determined.

A fraction of protryptases are converted to proteolytically active mature tryptase, which spontaneously forms donut-shaped tetramers and are stored in secretory granules in unstimulated MCs. Following activation, such as in IgE-mediated allergic reactions, the tetramers are released complexed to heparin proteoglycan and result in acutely elevated tryptase levels. If all four components of the tetramer are α- (α- homo-tetramer) the tryptase is proteolytically inactive; β- homo-tetramers and α/β— hetero-tetramers are both proteolytically active. The α/β— hetero-tetramer has altered substrate specificities from β- tryptase homo-tetramers. Only α/β-tryptase has been shown to induce vibration-triggered degranulation in both dermal and HLMC. This results from cleavage of the α subunit of the EGF-like module–containing mucin-like hormone receptor-like 2 (EMR2) mechanosensory receptor. The α/β-tryptase if present can selectively activate protease-activated receptor-2 (PAR2), which is expressed in smooth muscle, neurons, and alveolar endothelium. Released extracellular tetrameric tryptase dissociates over time into inactive monomers as its natural mechanism of inactivation.

Postulated roles for β-tryptase in pathophysiology remain to be established. Described actions include the degradation of the neuropeptide vasoactive intestinal peptide (VIP) and of muscle-relaxing neuropeptides, mitogenic effects on smooth muscle and epithelial cells, and inactivation of procoagulant proteins. Increased levels of tryptase in BAL fluid correlated to asthma severity, with severe asthma patients exhibiting the highest levels. While there were no differences in plasma tryptase levels between healthy volunteers and mild to moderate asthma patients, levels were significantly elevated in severe asthma patients and uncoupled from type 2 biomarker levels.[142]

Chymase is a serine protease that is essentially confined to MC. It is associated with heparin in a manner like tryptase. Although many activities continue to be reported in different pathophysiologic settings, the role of chymase in asthma and other airway disorders is not clearly defined.[143] Chymase may play a role in tissue remodeling. Substrates include angiotensin I, converting it to angiotensin II, VIP (inactivates), substance P, bradykinin, and kallidin (inactivates). Other activities include activation of matrix metalloprotease and stimulation of tissue neutrophilia and eosinophilia.[144]

Cathepsin G is a neutral protease with chymotryptic specificities. The concentration of cathepsin G in HLMC is roughly 100 to 700 ng/10^6 cells.[138] An elastase released from HLMC appears to be identical to human neutrophil elastase.[138] A measurement of 40 to 170 ng/10^6 cells assumes all HLMCs contain this enzyme, although it may be localized to an HLMC subset. Among carboxypeptidases, the MC carboxypeptidase A3 (CPA3), a zinc metallo-exopeptidase, is unique.[145] In eosinophilic type 2 asthma, CPA3 has recently been prominent in multiple gene signature studies.[146,147]

Granule-associated acid hydrolases include β-hexosaminidase, β-glucuronidase, and arylsulfatase.

■ Non-Preformed Mediators

Arachidonic acid metabolites are generated within minutes of MC activation and play a crucial role in the early phases of the asthmatic response. Cyclooxygenase metabolism in MC generates large quantities of prostaglandin (PG) D_2 and a small quantity of thromboxane A2.[65,148] PGD_2 can be produced by a number of cell types through the hematopoietic prostaglandin D2 synthase (H-PGDS). These cells include lung endothelial cells megakaryocytes, platelets, monocytes, T helper type 2 (T_H2) cells, and dendritic cells, although MCs are the predominant source of PGD_2. A lipocalin-type PGDS type is present in CNS and cardiac cells. PGD_2 is the most potent bronchoconstrictor of the cyclooxygenase metabolites. Additional actions of PGD_2 include induction of chemotaxis in eosinophils, basophils, and T_H2 cells, and increase in capillary permeability and vasodilation.

Although all tissue MCs generate PGD_2, not all generate significant quantities of 5-lipoxygenase products (e.g., lung >> skin). The major 5-lipoxygenase pathway products of HLMC are LTC_4, and LTB_4, with lesser quantities of 5-HETE. In IgE-mediated human lung challenges, HLMCs constitute the major source of released LTC_4,[149] although the LTC4 synthase is present in other cells including eosinophils, basophils, monocytes, macrophages, and dendritic cells. Cells such as neutrophils lack the ability to make LTC4 but can synthesize and secrete LTA4 to adjacent LTC4 synthase-competent cells to make LTC4. Released LTC4 is converted to LTD4 and LTE4. LTC4, D4 and E4 exert their effects through via three G protein–coupled receptors: CysLT1R, CysLT2R, and CysLT3R.[150] HLMCs express CysLT3R/GPR99[95], which is the high-affinity receptor for LTE4.[151] The consequences of LTE4 stimulation of HLMC are unknown but may prove important, as LTE4 is the most abundant of the leukotrienes in vivo due to its stability.

PAF is an early-phase phospholipid bronchoconstrictor that consists of a family of molecules. In contrast to the other lipid mediators, MCs appear to retain PAF intracellularly or demonstrate rapid reuptake of any that may be released. IgE-mediated activation of MCs induces the release of PAF, which plays an important role in inflammation and can be pathologic if left unchecked. PAF induces histamine release, Ca^{2+} mobilization, and chemotaxis in MCs.[152] MCs are also a source of PAF-acetyl hydrolase, which degrades extracellular PAF as an autocrine regulatory mechanism.[153]

HLMCs synthesize and release T_H2-type cytokines, including IL-5 and IL-13, which are felt to be central to the evolution of the late-phase response.[154,155] Additional multifunctional cytokines, including IL-3, IL-6, IL-8, transforming growth factor beta (TGF-β), basic fibroblast growth factor (bFGF), and TNF-α, also are synthesized by HLMCs. In general, cytokine protein products are released over a 1- to 24-hour period following allergic activation. IL-4, a cytokine that virtually defines T_H2 immunity, is immunolocalized to HLMCs, which are rich in surface IL-4 receptors. However, generation of IL-4 mRNA and protein release by HLMCs has been reported by some, but not all, investigators.[154,156] TNF-α, stored preformed within MC granules, is in a unique position to exert diverse host defense effects in allergy and innate immunity.[157] Some studies suggest that increased expression of TNF-α within HLMCs may play a role in asthmatic airway inflammation and correlates with asthma severity.[158,159]

Amphiregulin, a member of the epidermal growth factor family, is secreted following FcεRI-mediated activation. Its effects include increasing mucin gene expression, which may contribute to the epithelial cell metaplasia and mucus hypersecretion of asthma.[160]

■ Pharmacologic Modulation of Mast Cell Function

Only a limited number of pharmacologic agents have been tested in vitro on HLMC activation–secretion. In general, these agents have been tested on human parenchymal MCs rather than those in bronchi or resident in BAL.[64,65,161] Moreover, inhibitory potency has been evaluated with anaphylactic degranulation rather than PMD, the latter being more characteristic of asthma.[162,163] Several receptors that inhibit MCs activate ITIMs (see above). The common classes of anti-allergic and/or anti-asthmatic drugs used in clinical practice have received most evaluation. To date, the β-agonist pharmacologic agents, as typified by fenoterol and salmeterol, are reported to be among the most potent global inhibitors of HLMC mediator release with concentrations that inhibit histamine release by 50% (IC_{50}) of $\leq 10^{-8}$ M. Less effective inhibitors include the theophylline-like phosphodiesterase inhibitor isobutylmethylxanthine (IC_{50} = 0.5 mM) and PGE_2 ($IC_{50} = 10^{-5}$ M). Although widely touted as "MC stabilizers," disodium cromoglycate and nedocromil sodium, which have been shown as agonists at G protein–coupled receptor 35 (GPR35),[164] poorly inhibit purified HLMC histamine release.[43,165] Inhibition of BAL MC activation by these agents is reportedly more striking.[166]

The effects of glucocorticosteroids on MCs are diverse, including both stimulatory and inhibitory effects on the transcription of select genes. Release of early-phase mediators (e.g., histamine, LTC_4) in vitro and acute airway responses in vivo are unaffected by short pretreatment (up to 24 h) with these drugs. In contrast, IgE-mediated generation of TH2-type late-phase cytokine mRNA and protein (e.g., IL-5, IL-13) are suppressed ($IC_{50} = 10^{-8}$–10^{-9} M).[167]

FK-506, a macrolide that binds to a specific binding protein, inhibits HLMC mediator release at low concentrations (0.1–300 nM). Cyclosporin A, which binds to cyclophilin, and auranofin, an orally absorbable gold compound, both inhibit HLMC mediator release.

Specific inhibitors of LT generation include direct 5-lipoxygenase enzyme inhibitors, such as A-60477 (Zileuton), and indirect inhibitors, such as MK-886, which bind to a protein termed 5-lipoxygenase–activating protein (FLAP). Interestingly, PGD_2 release is markedly enhanced by FLAP inhibition. This phenomenon has been termed a "reverse shunt effect." Generally, 5-lipoxygenase pathway inhibitors do not affect HLMC histamine release. Cyclooxygenase-1 inhibition plays a critical role in a certain subset of "aspirin-sensitive" asthmatic patients. Agents such as indomethacin potently inhibit HLMC PGD_2 generation (IC50 = 5.5×10^{-10} M) while producing significant enhancement of LTC_4 release.

Stem cell factor and its receptor c-kit are critical for MC homeostasis. The drug imatinib inhibits multiple tyrosine kinases including c-kit. Severe asthmatics treated for 6 months with imatinib, a drug that has been used in chronic myeloid leukemia, showed diminished MCs in endobronchial biopsies, reduced AHR, and decreased serum tryptase compared with severe asthmatic controls.

These results support the crucial role MC and c-kit contribute to severe asthma pathogenesis.[168]

Omalizumab, a humanized monoclonal antibody, prevents binding of free IgE to the FcεRI-receptor on MC and basophils and inhibits surface FcεRI expression.[169] It is indicated in moderate to severe allergic asthma where it improves symptoms and quality of life and decreases exacerbations.[170]

Mast Cells in Pulmonary Disease

MCs have been implicated in a variety of pulmonary disorders based, to a great extent, on their presence in increased numbers and/or percentages in diseased tissues and the recovery of increased concentrations of MC-derived mediators, particularly histamine, in BAL fluid.[171,172] Implicated pulmonary disorders include asthma, idiopathic pulmonary fibrosis, sarcoidosis, hypersensitivity pneumonitis, pulmonary hypertension, cystic fibrosis, and chronic bronchitis.[47,173–176] The impact of MCs in common pulmonary diseases is highlighted below.

Asthma

MCs within airway epithelium are in an ideal sentinel position to be exposed to inhaled inciting stimuli. Intraepithelial MCs (IEMCs) produce tryptase but seldom chymase except in severe asthma[55,57] and were traditionally thought to represent the classic MCT phenotype. More recent reports assert that intraepithelial MCT in "T_H2-high" asthma also expresses CPA3, which had previously been identified only in association with MCTC.[145,177] A similar pattern is noted in asthmatic sputa, which more often show gene expression signatures for tryptase and CPA3 compared with healthy controls.[178] At baseline, even very mild asthmatics show evidence of continuous MC degranulation in bronchial mucosa and increased histamine content in BAL. Analysis of BAL in allergen-challenged atopic subjects and asthmatics demonstrates increased release of histamine, tryptase, and PGD_2. Increased numbers of luminal MC are also noted and correlate with mediator content, airflow obstruction, eosinophil numbers, and bronchial hyperresponsiveness. In general, asthmatic MCs exhibit ultrastructural evidence of degranulation. In nonfatal asthma, there is a significant increase of MCs within airway smooth muscle and mucosal gland stroma.[58] Multiple redundant MC mediators likely contribute to increased mucus gland secretion and smooth muscle constriction. Following chronic corticosteroid treatment, allergic reactions are diminished in association with depletion of MCs in both the epithelium and submucosa.

Although much attention has been given to IgE-mediated mechanisms of asthmatic airway activation, it is likely that multiple other MC-triggering mechanisms operate under a variety of immunologic, occupational, and environmental conditions. One mechanism proposed for EIA relates to airway cooling and the generation of hyperosmolarity on the dried airway surface leading to MC degranulation.

Up to 10% of asthmatics are intolerant of aspirin and other non-structurally related nonsteroidal anti-inflammatory drugs (NSAIDs). In vitro pretreatment of human airway tissues with indomethacin results in increased LTC_4 generation following IgE-mediated stimulation. MCs are the principal cells expressing LTC_4 synthase in the airways of aspirin-exacerbated asthmatics,[179] and these patients have increased Cox-2-expressing bronchial MC numbers.[180]

Pulmonary Fibrosis

The cellular composition of diffuse fibrotic reactions includes striking increases in MC numbers. MCs synthesize and release important mediators of fibrosis, including TGF-β and bFGF.[16–19,181] Most bFGF$^+$ cells in lung interstitium are HLMCs, a finding most prominent in idiopathic pulmonary fibrosis. Also, their distribution matches that of extracellular matrix deposition. The hypothesis that MCs and their mediators are critical to the development of fibrotic reactions is supported by animal models in which MC hyperplasia has been a constant finding in pulmonary fibrosis induced by bleomycin, ionizing radiation, and asbestos. Bronchial remodeling with subepithelial fibrosis is also a prominent feature of the asthmatic airway. It is not clear whether MC proliferation and activation drive and/or are secondary to the fibrotic process. The latter mechanism could be affected through fibroblast generation of SCF, producing MC proliferation, chemotaxis, and inhibition of apoptosis.

Respiratory Infections

Recently, novel functions for MCs as regulators of immune responses to infections have been elucidated. Like other innate immune leukocytes, MCs express a gamut of both surface and cytoplasmic pattern recognition receptors that afford the capability to recognize fungi, viruses, and bacteria.

Fungi make up the most abundant class of eukaryotic organisms found in the environment, and fungal antigens are the most common aeroallergen that trigger allergies. Environmental fungi such as *Aspergillus fumigatus* and *Alternaria alternata* are common allergens thought to play a role in asthma pathogenesis.[182] Although fungal interaction with the host is most commonly on the mucosal surfaces where MCs are localized, MC functions during fungal contact or infection are poorly understood and under-investigated. While *A. fumigatus* directly triggers MC activation in vitro[183] the possibility that MCs are triggered directly in vivo has not been fully elucidated. Fungi induce IL-33 production in the lungs, and airway epithelial cells are prominent producers of this cytokine that activates MCs.[184–187]

The respiratory tract is bombarded with environmental agents both innocuous and pathogenic. Viruses are common culprits that threaten the physiology of the respiratory tract and can cause life-threatening disease in patients. Influenza A virus (IAV), rhinovirus, coronavirus, respiratory syncytial virus (RSV), adenovirus, parainfluenza virus, and bocavirus are common circulating viruses that can cause mild to severe disease in humans. Early-life infection with RSV can cause asthma development in later life.[188] RSV can directly interact with MCs, inducing their degranulation in addition to causing their activation through epithelial cell infection.[189] Excessive MC activation/degranulation has been linked to severe pathologies associated with influenza and dengue viruses.[190,191] Host protective roles for MCs during respiratory virus infections have recently been elucidated wherein viral RNA activation of TLR3 promotes the production of type I and III interferons by MCs[192] and helps recruit CD8$^+$ T cells.[193] As MCs express TLR2 and TLR4 on the cell surface, in addition to complement receptors that bind opsonized complement proteins, MCs can be activated by bacteria both directly and indirectly, and can play a role in bacterial containment and killing.[194,195]

Murine Mast Cells

Like in the human, mice have MCs that take up primary residence in the respiratory mucosa where MC recruitment increases after allergenic or viral triggers.[196] Mouse MCs are phenotypically and physiologically comparable to human MCs and can be visualized in both hematoxylin and eosin stains as well as toluidine blue stains. Figure 21-3 shows several MCs in the connective tissue around the upper airways of a mouse subjected to an *Aspergillus fumigatus*–induced asthma model.[197] MC progenitors (Lin$^-$Kit$^+$Sca-1$^-$Ly6c$^-$FcεRIα$^-$CD27$^-$β7$^+$ST2$^+$) have been identified in the adult mouse bone marrow[198] to support the ability to generate MCs as needed in adult animals. The availability of MC-deficient mice (*Kit*$^{W/Wv}$,

$Cpa3^{Cre/+}$, and *Mcpt5-Cre*) has aided investigation of the role and immunoregulatory functions of MCs in health and disease.[199–201]

MAST CELL–EOSINOPHIL INTERACTIONS

Since shortly after their discovery, it has been recognized that MC and eosinophils home to many of the same tissues, particularly in the setting of allergic and other inflammatory conditions. Not surprisingly, therefore, researchers have identified a variety of crosstalk between these two cell types that involves both soluble and physical cellular interactions.[202] For example, eosinophil granule proteins can trigger histamine, PGD$_2$, and cytokine release from human MC.[203,204] Eosinophils also produce important MC survival and activation factors, such as SCF and nerve growth factor (NGF).[205] Conversely, in human lung IgE-mediated hypersensitivity reactions, the major cellular source of the "lifeblood" of eosinophils, IL-5, is the HLMC.[154] PGD2 activates the eosinophil PGD2 receptor 2 (DP2; previously CRTH2) producing chemotaxis.[206] Histamine also activates eosinophils through the H3 receptor[206] and also what is now known as the histamine H4 receptor.[207] Histamine and PGD$_2$ have been shown to augment synthesis of LTC$_4$ in human eosinophils.[206] MC-derived TNF-α induces eosinophil GM-CSF release and autocrine survival enhancement,[208] and MC tryptase induces eosinophil IL-6 and IL-8 secretion.[206,209] In addition, MC chymase suppresses eosinophil apoptosis and increases adhesion molecule expression, chemokinesis, and cytokine and chemokine release by human eosinophils.[210] Not all MC–eosinophil interactions are proinflammatory, however, as it has been shown that MC tryptase can cleave and inactivate the eosinophil chemokines CCL5 and CCL11.[211] The opposing charges of each cell's granule contents, mast cells having a relative negative charge while eosinophil granule proteins are positively charged, also is considered to afford the relative blockage of effector functions of each cell.[212] Additionally, MC enzyme β-tryptase can cleave eosinophil chemoattractants[211] to limit eosinophil migration into mucosal tissue. Thus, MCs and eosinophils communicate bidirectionally in complex ways that may amplify or potentially modulate the inflammatory response.

EOSINOPHILS

While eosinophils are considered leukocytes, like MCs, they in fact reside primarily in the tissues. Indeed, the ratio of tissue to blood eosinophils is estimated to be 100:1 or greater. Under normal circumstances, the major resident population of eosinophils is in the lamina propria of the gastrointestinal tract. Eosinophils are also present in the thymus, as well as the uterus and developing mammary gland in females. In the absence of disease, very few eosinophils are found in the lung (although resident eosinophil populations have recently been identified in mouse lungs). On the other hand, large numbers of eosinophils traffic to the lungs and other tissues in the setting of allergic diseases, helminthic parasite infections, and certain other pathologic states.

■ Eosinophil Origins and Development

Eosinophils have been evolutionarily conserved, with eosinophil-like cells identified in invertebrates and in early order vertebrates. Eosinophils develop in the bone marrow from hematopoietic stem cell precursors. The immediate eosinophil precursor is a common eosinophil–basophil progenitor. Specific differentiation to the eosinophil lineage involves coordinated expression of the transcription factors, GATA-1, PU.1, and C/EBP. Among these, GATA-1 plays a central role, since mice with deletion of a high-affinity GATA-binding site in the GATA-1 promoter (ΔdblGATA1 mice) lack mature eosinophils, without loss of other hematopoietic lineages.[213] $CD34^+$ stem cells that are $CD38^+IL5RA^+IL3RA^+CD45RA^-$ give rise to eosinophils exclusively.[214,215] The cytokines IL-3, GM-CSF, and IL-5 stimulate growth and differentiation of eosinophils in the bone marrow, and IL-5 plays an essential role in stimulating bone marrow production of eosinophils and triggering their release into the circulation.[216] A common basophil–eosinophil progenitor cell population that expresses low levels of CD133 on the cell surface also has been identified circulating in the blood.[217,218]

IL-5 is produced by lymphocytes and endothelial cells in the bone marrow, as well as by lymphocytes and parenchymal cells in the lung and other tissues. The importance of IL-5 in eosinophilopoiesis is demonstrated by the fact that transgenic mice overexpressing IL-5 develop profound blood and tissue eosinophilia.[219] IL-5 production by resident B cells in the bone marrow, spleen, and Peyer's patches likely support the presence of resident eosinophils in these tissues at baseline.[220] IL-5 knockout mice have markedly reduced numbers of eosinophils at baseline, and they fail to develop eosinophilia in response to allergen sensitization and challenge.[221] These and other findings have provided the impetus for the development of IL-5 and IL-5 receptor–targeted monoclonal antibodies as therapeutics for asthma and other eosinophilic diseases, as discussed below.

■ Morphology and Structure

The mature human eosinophil has a diameter of 12 to 17 μm, slightly larger than the neutrophil. The nucleus is usually bilobed, and the cytoplasm contains characteristic granules that stain pink with eosin. The distinctive features of eosinophil granules can be seen clearly by electron microscopy (Fig. 21-4). Primary granules, which appear during the promyelocytic stage of development, are round, membrane-limited structures that contain Charcot–Leyden crystal (CLC) protein.[222] Secondary (also termed specific or cytoplasmic crystalloid) mature granules appear later during eosinophil differentiation,[223] are more numerous, and appear as oval or elongated trilaminar membrane-bound structures with a dense crystalline core and less dense matrix.[222] The mature granule core contains major basic protein (MBP), while other granule proteins (eosinophil

cationic protein [ECP], eosinophil-derived neurotoxin [EDN], and eosinophil peroxidase [EPO]) are in the matrix. A plethora of premade cytokines and chemokines also are stored within the granule matrix. Intriguingly, in resting eosinophils, approximately 8% of the eosinophil granules are found in various stages of the emptying process. The number of emptying granules increases significantly when eosinophils are activated.[224]

Eosinophil LBs were misidentified as granules in the past due to technical limitations. Based on TEM images, they are now recognized to be electron-dense, round organelles of varying size, without a true bilayer-membrane demarcation.[225] These lipid-rich organelles localize arachidonic acid–metabolizing enzymes and serve as sites of eicosanoid synthesis,[226] as well as storage of some cytokines like TNF-α.[227] The number and size of LBs increase with eosinophil activation. Eosinophil LBs associate with the endoplasmic reticulum, suggesting that they may play a role in protein synthesis.[225]

■ Eosinophil Recruitment

Current knowledge about the mechanisms of eosinophil recruitment into tissues is based largely on studies of asthma and allergic diseases, but these mechanisms may operate in other eosinophilic disorders as well. The initial step in eosinophil recruitment involves priming, which converts the resting cell to an adhesive, migratory, and activation-sensitive phenotype. Priming likely results from exposure to IL-3, IL-5, GM-CSF, and chemokines such as CCL11 (eotaxin-1), particularly in allergic individuals, in whom these factors are elevated in the circulation.[228–231] TNF-α, LTs, and other inflammatory mediators may prime eosinophils as well. Once primed, eosinophils make contact with the blood vessel wall and undergo rolling, mediated by E- and P-selectins on endothelial cells, which can be upregulated by IL-1 and TNF-α, and L-selectin that is constitutively expressed on the eosinophil.[232–235] Rolling activates eosinophil integrins, which mediate tight adhesion through high-affinity binding to endothelial cell adhesion molecules. The eosinophil integrins, VLA-4 ($\alpha 4\beta 1$ or CD49d/CD29) and CD11b/CD18, and their respective endothelial counter-ligands VCAM-1 and ICAM-1, constitute the most important binding pairs responsible for firm adhesion to the vessel wall. IL-4 and IL-13 increase VCAM-1 expression on endothelial cells.[236,237] Because VLA-4 (binding partner for VCAM-1) is highly expressed on eosinophils, but not neutrophils, this represents a mechanism for selective eosinophil recruitment to sites of allergic inflammation.[233,238] Integrin-mediated firm adhesion is followed by diapedesis, or transmigration across the endothelium. Eosinophils are further activated by endothelial transmigration, which also increases their ability to survive.[239] Based on in vitro studies, eosinophils can probably survive in tissues for two weeks or longer.

Upon entering tissue, eosinophils shift from β1- to β2-integrin–dominated interactions under the influence of chemokines such as CCL24 (eotaxin 2),[240] and migrate along chemoattractant gradients. Multiple factors are known to be chemotactic for eosinophils, including PAF, LTB_4, complement factors C3a and C5a, GM-CSF, IL-3, IL-5, IL-16, and the chemokines CCL3 (MIP-1α), CCL5, CCL7 (MCP-3), CCL11, CCL24, CCL26 (eotaxin 3), and CXCL8 (IL-8). Among these, IL-5 and the eotaxins (CCL11, CCL24, and CCL26) are the most highly selective for eosinophils, making them attractive as therapeutic targets. Indeed, monoclonal antibodies directed against IL-5 and the IL-5 receptor are now approved for treatment of severe eosinophilic asthma. In addition, a variety of agents that block CCR3, the receptor for eotaxins and several other eosinophil-active chemokines, are currently in clinical trials for treatment of eosinophilic asthma. The results of some of these studies are discussed at the end of this chapter.

■ Heterogeneity and Localization

Phenotypic and physiologic differences have been observed in peripheral blood eosinophils and tissue localized eosinophils. Eosinophil density (granularity), potential for respiratory burst, metabolism, surface expression of markers, and the ability to regulate other leukocytes vary based on locale.[241–243] Most tissue localization occurs neonatally or during early postnatal days. Thymic eosinophils have an activated phenotype with low CD62L and high CD69 expression, and they are considered to participate in T cell selection and education.[244] Intriguingly, the female reproductive tract and mammary glands are sites of high tissue localization for eosinophils where they are considered to play roles in uterine and mammary duct development and remodeling.[245–247] Eosinophils are also located in mucosal tissue at homeostasis, where they are hypothesized to play regulatory functions. For example, eosinophils in the gastrointestinal tract mucosa may regulate the functions of Paneth cells, goblet cells, and B cells.[248] While IL-5 is the major attractant for eosinophils to take up residence at these sites, infiltration and residence can occur even in the absence of IL-5. Mouse models have been of extreme importance in delineating eosinophils functions during disease, as tissue eosinophils are difficult to access in human patients. Mouse eosinophils closely resemble human eosinophils in phenotype, physical characteristics, and functions.[249] As shown in Fig. 21-5, mouse eosinophils marginate the peribronchial spaces in a fungal model of allergic asthma, similar to observations in human asthmatics.

■ Eosinophil Activation and Degranulation

The priming process required for eosinophil recruitment also represents the initial phase of eosinophil activation. IL-5 is the most

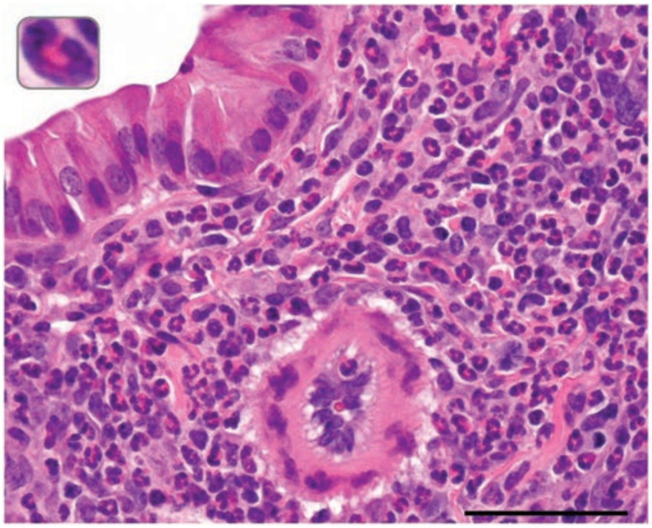

Figure 21-5 Localization of mouse eosinophils around the airways after allergen provocation and challenge. *Aspergillus fumigatus* antigen–sensitized C57BL/6J mice challenged via inhalation of airborne *A. fumigatus* live conidia result in peribronchovascular inflammation with eosinophil dominance. Photomicrograph reproduced with permission from Veterinary Pathologist, Dr. Peter Vogel at St. Jude Children's Research Hospital, Memphis, TN.)*

important cytokine for priming of eosinophils in vivo.[229,250] IL-5 binds to heterodimeric receptors on the eosinophil surface, consisting of a ligand-specific α chain and common β chain that is also found in the receptors for IL-3 and GM-CSF. Binding of IL-5 to its receptor triggers a variety of intracellular signaling cascades, which enhance multiple eosinophil functions, including the response to chemotactic factors, integrin-mediated adhesion, agonist-stimulated LTC_4 and superoxide generation, phagocytosis, and helminthotoxic activity.[229,231,251–254] IL-3 and GM-CSF stimulate these functions on eosinophils as well. As noted earlier, IL-5, IL-3, and GM-CSF also enhance eosinophil survival. The effects of all three cytokines are antagonized by glucocorticoids, which induce eosinophil apoptosis.[255,256]

Eosinophils are primed in the circulation of patients with asthma and hypereosinophilic states, resulting in greater functional responses when blood eosinophils from such individuals are studied in vitro, in comparison to cells from normal controls.[229] In vivo priming also has been demonstrated in eosinophils obtained by BAL following antigen instillation into the lungs of allergic subjects (segmental allergen challenge).[257] Intriguingly, eosinophils within the airways can be activated by respiratory viruses, evidenced by upregulation of eosinophil survival marker IL-5Rα in addition to CD69 and adhesion molecules.[258,259]

Eosinophils express a number of surface receptors that can mediate cell activation. These include receptors for immunoglobulins (IgA, IgG, and IgE), complement components (C3a and C5a), eicosanoids (LTB_4, cysteinyl LTs, and PGD_2), and PAF, as well as numerous cytokines and chemokines. Priming can upregulate cell surface expression and/or activation of specific receptors,[260] and may induce new expression of receptors not normally present on resting eosinophils, such as the high-affinity IgE receptor FcεRI.[261] Ligand binding to many of these receptors triggers responses that include degranulation, lipid mediator synthesis, and generation of reactive oxygen species. Various ligands activate distinct signaling cascades within the cell, resulting in stimulus-specific differential activation of eosinophil effector functions.

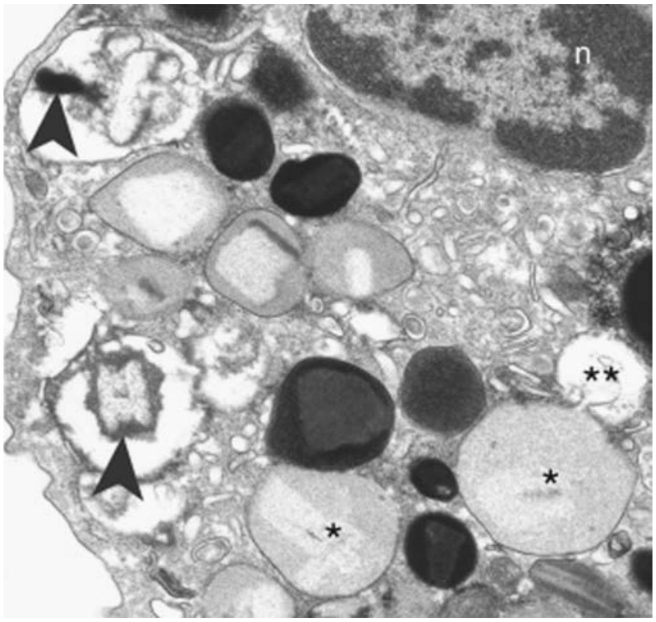

Figure 21-6 Ultrastructure of a human blood eosinophil activated in vitro with CCL11 (eotaxin). Specific granules undergoing piecemeal degranulation exhibit lucent areas in their cores, matrices, or both. Granules with residual cores *(arrowheads)*, reduced internal electron density (*) and membrane empty chambers (**) are shown. *(Reproduced with permission from Melo RCN, Perez SAC, Spencer LA, et al. Intragranular vesicotubular compartments are involved in piecemeal degranulation by activated human eosinophils. Traffic. 2005;6(10):866–879.)*

As in MCs, the principal mode by which granule-associated proteins are released from human eosinophils is PMD.[223,224,262,263] This process involves secretion of specific granule contents in discrete packets, without granule-to-granule or granule-to-plasma membrane fusion. An eosinophil undergoing PMD in vitro is illustrated in Fig. 21-6. Electron microscopic studies reveal that PMD is associated with the development of complex vesicotubular networks within emptying granules.[262,263] Interestingly, intracellular cytokine receptors within granules and secretory vesicles play a key role in transporting and guiding selective secretion of their cognate cytokines, allowing for stimulus-specific, selective, and sequential release of cationic granule proteins and stored cytokines and chemokines.[264] In addition, receptors for cysteinyl LTs have been demonstrated on eosinophil granule membranes, where they may mediate secretion of granule contents from intact cells in response to endogenously generated LTC_4 or secretion from cell-free granules triggered by extracellular LTD_4.[265] Intriguingly, mouse eosinophils undergo PMD after contact with respiratory viruses,[266,267] although the clinical relevance of this phenomenon remains to be determined.

Besides PMD, eosinophil granules may be emptied through classic or compound exocytosis pathways. In classic exocytosis, the granule membrane fuses with the plasma membrane, releasing granule contents into the extracellular space. In compound exocytosis, several granules fuse intracellularly prior to fusing their membranes with the plasma membrane. These two processes have not typically been observed in vivo.[268] Compound exocytosis involves SNARE family transport docking and vesicle fusion proteins.[269] Finally there is also cytolytic degranulation, leading to the appearance of cell-free eosinophil granules in tissue in certain eosinophilic diseases.[223] Whether this is a regulated process or the result of eosinophil necrosis at sites of inflammation is not known.

■ Eosinophil Granule Proteins

Eosinophils contain a variety of cationic granule proteins that have toxic effects on parasitic helminths and RNA viruses, as well as on

AL GRAWANY

host cells. In addition, a variety of other proteins, including enzymes and cytokines, are stored in and released from eosinophil granules. MBP, a highly basic protein that accounts for more than half of eosinophil granule protein mass, is found in the crystalline core of specific granules.[270] MBP is synthesized as a preproprotein, which is cleaved to a 13.8-kDa highly cationic molecule during eosinophil maturation. The pro-peptide, which is anionic, is thought to protect the developing eosinophil from the toxic effects of the highly cationic mature MBP. Low levels of MBP are expressed in basophils, consistent with their close lineage relationship to eosinophils. MBP is directly toxic to larvae of *Schistosoma mansoni*, *Trichinella spiralis*, and other helminths, supporting a role in host defense against parasites.[271] Several lines of evidence have suggested that MBP could be an important mediator of asthma. MBP inhibits ciliary function and is toxic to respiratory epithelial cells.[272,273] When administered to the airways of nonhuman primates, MBP caused transient bronchoconstriction followed by persistent bronchial hyperresponsiveness.[274] In addition, MBP was shown to bind to and inhibit M2 muscarinic receptors, increasing vagally mediated bronchoconstriction in guinea pigs.[275] On the other hand, mice deficient in MBP showed no attenuation of airway histopathologic changes or airway hyperreactivity in an allergen-induced asthma model,[276] suggesting that MBP does not play an essential role in allergic airway disease, at least in the mouse. While the effect MBP has on respiratory viruses is yet to be fully elucidated, MBP trapped in eosinophil extracellular traps may have antibacterial properties.[277]

Both ECP and EDN are highly basic proteins found in the matrix of specific granules. ECP and EDN are homologous proteins (67% amino acid sequence identity), the result of gene duplication, that are also similar to human pancreatic ribonuclease (RNase) A.[271] Indeed, both ECP and EDN are active RNases, with the ability to inactivate RNA viruses such as RSV and IAV.[259,271] EDN was initially described as a neurotoxin that causes severe damage to myelinated neurons, a property possessed by ECP as well. This activity may account for the neurologic abnormalities seen in patients with hypereosinophilic syndrome (HES) and cerebrospinal fluid eosinophilia. Like MBP, ECP and EDN are both helminthotoxic.[271] Levels of ECP are elevated in blood, BAL fluid, and sputum in patients with asthma, and have been found to correlate with disease severity.[278] For this reason, ECP levels in blood or sputum are often monitored in asthma clinical trials as a means of assessing response to treatment.

Similarly, EPO is also a highly basic protein found in the matrix of specific granules. EPO is a unique peroxidase expressed only in eosinophils. In the presence of H_2O_2, EPO oxidizes halide ions to form highly reactive hypohalous acids. Bromide is the preferred substrate, leading to hypobromous acid (HOBr), an extremely potent oxidant that damages DNA and other critical cellular targets. EPO plus H_2O_2 and halide ions can kill parasites, bacteria, and mycobacteria, as well as MCs and tumor cells.[279] The potential role of EPO in allergic airway disease has been explored in mice with targeted deletion of the EPO gene. In this study, despite a marked reduction in bromo-oxidation of lung proteins, EPO deficiency did not result in any attenuation of allergen-induced airway inflammation or bronchial hyperresponsiveness,[280] indicating that EPO is not essential for development of allergic pulmonary pathology in the mouse. The combination of ECP, EDN, and EPO affords eosinophils antipathogenic effector functions against several classes of pathogens.[277]

CLC protein localizes to the primary eosinophil granule and is also expressed in basophils. The protein readily crystalizes to form bipyramidal CLCs, often seen in affected tissues and considered a hallmark of eosinophil-associated diseases in humans. Previously thought to possess lysophospholipase activity, CLC protein has been shown to belong to the galactose-binding lectin family (galectins) and to avidly bind mannose sugar.[281] Despite the long-recognized association of CLCs with eosinophil infiltration of tissues, the role of CLC protein in eosinophil-related pathology is unknown.

Eosinophils also contain within their granules various other enzymes, including β-glucuronidase, arylsulfatase B, and matrix metalloproteinase-9 (MMP-9), as well as a plethora of preformed cytokines and chemokines, which can be released in regulated fashion when stimulated.

■ Other Eosinophil Contents

A variety of chemical and immune mediators are pre-stored in eosinophil granules and LBs and some may be synthesized de novo upon stimulation. In addition to eosinophil-specific granule proteins, these additional eosinophil contents allow them to crosstalk with other members of the immune system and regulate immune functions.

Lipid Mediators

Upon stimulation, eosinophils produce large quantities of the 5-lipoxygenase–derived eicosanoid, LTC_4. Synthesis of LTC_4 in eosinophils occurs at the nuclear membrane[251,282] and in cytoplasmic LBs.[283] Following secretion, LTC_4 is converted extracellularly to LTD_4 and LTE_4. These cysteinyl leukotrienes act through cysLT1 and cysLT2 receptors to cause bronchoconstriction, stimulate mucus secretion, promote synthesis of T_H2 cytokines, and contribute to airway remodeling.[284] The ability to block these effects underlies the beneficial actions of cysLT receptor antagonists and LT synthesis inhibitors in asthma. Other biologically active lipids produced in substantial quantities by eosinophils include 15-HETE, 5-oxo-ETE, and PAF. However, the roles of these products in asthma and other eosinophil-associated diseases remain unclear.

Cytokines and Chemokines

Classically, eosinophils were considered terminal effector cells of inflammatory responses, acting by secretion of granule proteins and the acute release of other mediators. However, it is now recognized that eosinophils synthesize a wide array of cytokines and chemokines, equipping them to participate in the regulation of immune and inflammatory responses. The major cytokines and chemokines expressed in eosinophils are listed in Table 21-1. Interestingly, a number of these factors have autocrine or paracrine effects on eosinophils themselves. Most notably, IL-3, GM-CSF, and IL-5, which are produced by activated T lymphocytes and other cells, including MCs and eosinophils themselves, enhance eosinophil survival and activate eosinophil function in vitro and in vivo.[251–253,257,285–289] In another example, IL-16, a product of eosinophils and other cells, triggers rapid eosinophil release of CCL5 (RANTES), which generates autocrine signals that augment release of LTC_4 and IL-4.[290] A number of cytokines and chemokines synthesized by eosinophils are stored within granules. When the cells are stimulated, these preformed cytokines are released by PMD.

Eosinophil-derived cytokines likely contribute to the regulation of inflammatory responses in eosinophil-associated diseases and drive specific pathophysiologic responses. For example, elaboration of T_H2 cytokines amplifies allergic responses, and is likely important in host defense against parasites and tissue remodeling and repair. TGF-α released by eosinophils is a potent stimulus for synthesis of mucins by airway epithelial cells,[291] which contributes to asthma and other eosinophilic airway diseases. Also, accumulating evidence implicates eosinophil-derived TGF-β as a driver of airway remodeling in asthma[292] and suggests a link to pulmonary fibrosis as well.[293]

Eosinophil involvement in local immunity and or remodeling or repair (LIAR), as proposed by Lee and colleagues in 2010, posits that eosinophils are recruited into tissues that are undergoing alterations in response stimulus and engage in regulatory processes that lead to resolution of inflammation and repair processes.[294] Eosinophil-derived cytokines are also important in the regulation of female reproductive development, adipose tissue maintenance, and B cell regulation.[295] A clearer understanding of the roles of eosinophil-related cytokines in human diseases will emerge as additional therapeutic agents designed to target specific cytokines, their receptors, and downstream signaling pathways are tested in clinical trials.

Reactive Oxygen Metabolites

Like neutrophils, eosinophils synthesize superoxide anion ($O_2\bullet^-$) and H_2O_2 through the action of NADPH oxidase. Notably, NADPH oxidase components are more highly expressed and more readily activated in eosinophils than neutrophils, endowing stimulated eosinophils with a greater capacity to produce $O_2\bullet^-$ and H_2O_2.[296] As discussed previously, eosinophils produce HOBr through the action of EPO on bromide and H_2O_2.[279] In a reaction involving HOCl and $O_2\bullet^-$, EPO also catalyzes formation of hydroxyl radical ($\bullet$OH), the most reactive of all oxygen metabolites. As noted, EPO-derived oxidants kill parasites and other microorganisms, and thus may be important for host defense. By contrast, EPO appears not to play a key role in allergic airway disease in mice.[276,280]

In addition to reactive oxygen species, eosinophils also generate nitric oxide through nitric oxide synthase activity to react with superoxide anions to form highly cytotoxic compound peroxynitrite. These reactive nitrogen species play a role in antiviral defense mechanisms during RSV and parainfluenza virus infections.[297,298] The importance of eosinophil-derived oxidants in human health and disease is at present uncertain and requires further study.

Immunoregulatory Capacity of Eosinophils

Recent investigations have demonstrated that human and mouse eosinophils can process antigen, express major histocompatibility complex II (MHC-II) and co-stimulatory molecules, and function as "professional" antigen-presenting cells.[299,300] In mice, eosinophils within the airway lumen can migrate to regional lymph nodes where they stimulate antigen-specific T cell proliferation.[301] In addition, eosinophils synthesize, store, and secrete T_H2 cytokines and chemokines, granting them the capacity to initiate T_H2 differentiation of $CD4^+$ T cells as well as recruit T_H2 cells to sites of infection or allergen deposition, as demonstrated in several mouse models of allergen-induced airway disease and parasitic infection.[302] Thus, there is now substantial evidence, largely from murine models, that eosinophils play a central role in directing the T_H2 immune response. Additionally, eosinophils can support B cell differentiation to plasma cells, interact with plasmablasts, and promote the generation of long-lived plasma cells.[303,304] These findings emphasize that, beyond their cytotoxic and destructive potential, eosinophils contribute in complex ways to host defense and the pathophysiology of allergic disease. Mouse eosinophils also perform a putative antigen-presenting function during IAV infection, through upregulation of MHC-I and co-stimulatory marker expression, elevating migratory molecules and trafficking to draining lymphoid organs, and stimulating virus-specific $CD8^+$ T cell responses.[259,267] Whether eosinophils perform a similar function in human influenza infection remains to be elucidated.

Eosinophils and Host Defense

Many years ago, histopathologic evidence of eosinophils surrounding dying helminths in tissue biopsy specimens led to the hypothesis that eosinophils play a role in the immune response to multicellular parasites. Subsequently, it was demonstrated that, in the presence of antibodies or complement, eosinophils can kill parasites in vitro, as can purified eosinophil granule proteins.[305] Further support of a role for eosinophils in host defense against helminths came from epidemiologic studies that correlated high eosinophil counts with resistance to posttreatment reinfection with *Schistosoma* spp. in humans.[306] Moreover, studies of experimental helminth infections in mice depleted of eosinophils by IL-5 neutralization or gene targeting have indicated that IL-5 and eosinophils are important for protective innate immunity against a variety of parasites,[307–309] although the results are not all consistent.[310] Other studies of mice deficient in CCL11 or treated with a monoclonal antibody targeting the eotaxin receptor CCR3 have also demonstrated that eosinophils are important for clearance of parasites in vivo.[311,312] A recent study using mice made eosinophil-deficient by expressing the diphtheria toxin A gene under control of the EPO promoter (*PHIL* mice),[313] as well as mice lacking either MBP or EPO, showed that eosinophils kill parasite larvae during primary *Strongyloides stercoralis* infection by a mechanism dependent on MBP.[314] A consistent finding in a number of these studies is that eosinophils play an important role in host defense during primary parasite infection, whereas they appear not to be essential for adaptive responses leading to protective secondary immunity.[309,311,312,314] Interestingly, other recent studies showed that survival of *Trichinella spiralis* was actually reduced in mice genetically ablated of eosinophils, and that parasite growth and survival were restored when the mutant mice were reconstituted with eosinophils by intravenous transfer; in this model, eosinophils enhanced parasite survival by promoting accumulation of T_H2 lymphocytes and preventing induction of inducible NO synthase in macrophages and neutrophils at sites of disease.[315,316] Thus, while substantial evidence indicates that eosinophils are protective in the innate immune response to many parasites, the roles they play in helminthic infections are complex and depend on interactions with other immune cells.

As noted earlier, human ECP and EDN are both RNases, and can inactivate RSV in vitro.[271] Mouse eosinophils express a diverse array of eosinophil-associated RNases (EARs) with the ability to inactivate pneumonia virus of mice (PVM),[317] a major pathogen in rodents that is closely related to RSV. More recently, it has been demonstrated that hypereosinophilic IL-5 transgenic mice exhibit enhanced virus clearance when infected with RSV,[318] and that activated eosinophils recruited to the lung in a model of allergen-induced airway disease are profoundly antiviral and promote survival in an otherwise lethal PVM infection.[266] Eosinophils also function as antigen presenters that activate $CD8^+$ T cells promoting their priming, activation, and cytokine production through epigenetic regulation during IAV infection.[258,267] Viral-induced damage to the respiratory epithelial cell barrier is a significant effect of IAV infection. Although eosinophil products can be cytotoxic,[319] eosinophils protect the respiratory epithelium from IAV-induced cytopathology,[259] indicating that eosinophil functions at the mucosa are complex and multifaceted. Parainfluenza virus infectivity is directly reduced by eosinophils through nitric oxide generation.[298] Thus, while they contribute to the pathophysiology of allergic airway disease, activated eosinophils have the capacity to mediate effective antiviral host defense in the mouse. Further studies are needed to define the role of eosinophils in the immune response to viral infection in humans.

Human MBP and ECP also possess bactericidal activity, and various bacteria can induce degranulation of human eosinophils in vitro.[271] In addition, human eosinophils are able to kill *Escherichia coli* by a mechanism involving NADPH oxidase- and EPO-generated oxidants in vitro.[271] Similar to neutrophil extracellular DNA traps, eosinophils release DNA to form traps that serve as a scaffold for their cationic granule proteins to limit bacterial growth and dissemination.[320–322] Despite these observations, few data exist to implicate a role for eosinophils in host defense against bacterial infections in vivo. Eosinophil responses to respiratory pathogens have been reviewed in depth elsewhere.[277] Cumulatively, ascribed functions

TABLE 21-2 Eosinophilic Lung Diseases

Asthma
Allergic bronchopulmonary aspergillosis/mycosis
Eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome)
Simple pulmonary eosinophilia
Chronic eosinophilic pneumonia
Acute eosinophilic pneumonia
Helminthic infections
Drug hypersensitivity reactions
Hypereosinophilic syndrome

of eosinophils at the pathogen interface further support the LIAR hypothesis that eosinophils are not necessarily tissue destructive.[294]

Eosinophil–Disease Associations

Peripheral blood eosinophilia and eosinophilic lung inflammation are common in a variety of pulmonary conditions, including those listed in Table 21-2. The clinical manifestations and treatment of these disorders are discussed in detail elsewhere in this textbook.

Among eosinophilic lung diseases, asthma is by far the most common and most well studied. Over the years, much evidence has accumulated supporting a key role for eosinophils in the pathogenesis of asthma. Among the numerous animal studies addressing this question, most compelling are those involving genetically eosinophil-deficient (ΔdblGATA1 and *PHIL*) mice, which are protected against allergen-induced airway hyperresponsiveness, allergic airway inflammation, mucus hypersecretion, and peribronchiolar collagen deposition.[213,313,323,324] In humans with asthma, eosinophils and their specific products (e.g., ECP) increase in the airway lumen and airway wall during spontaneous exacerbations and following experimental allergen challenge.[287,325,326] Sputum eosinophil numbers and ECP levels also correlate with asthma severity.[278] When asthma improves, either spontaneously or in response to treatment, eosinophils and their products decline.[327,328] Corticosteroids, the most effective therapy for asthma, have potent anti-eosinophil effects.[329] Also, an inhaled corticosteroid treatment strategy directed specifically at reducing sputum eosinophils resulted in significantly better asthma control than treatment based on standard asthma guidelines.[330] Finally, as discussed in the next section, specific eosinophil-targeted therapy with an IL-5-neutralizing monoclonal antibody has been shown to reduce exacerbations and facilitate steroid tapering in patients with severe, oral corticosteroid–dependent asthma with high eosinophils.[331,332] It should however be emphasized that eosinophilia is primarily associated with “T2 high” asthma endotypes, and that in “non-T2” asthma, neutrophils, rather than eosinophils, likely play a key pathogenetic role.

HES is a rare disorder characterized by persistent marked blood eosinophilia (>1500/µL) or prominent tissue eosinophilia and eosinophil-induced organ damage or dysfunction, in which secondary causes of eosinophilia, such as parasitic or viral infections, allergic diseases, drugs, and hypoadrenalism have been excluded.[333] Pulmonary involvement is seen in 50% of cases. HES is classified as either myeloproliferative or lymphocytic, based on pathophysiology. The myeloproliferative form, exemplified by patients bearing the FIP1L1-PGDFRA fusion gene, which produces a constitutively active tyrosine kinase that drives eosinophil hyperproliferation, represents a type of myeloproliferative neoplasm. The tyrosine kinase inhibitor, imatinib mesylate, is useful in treatment of these patients. In lymphocytic HES, eosinophil proliferation is driven by T-cell overproduction of IL-5 and/or other eosinophil hematopoietins. Corticosteroids are the first line of treatment for these patients. The anti-IL-5 monoclonal antibody mepolizumab has also been shown to be effective in steroid-requiring lymphocytic HES.[334,335]

In addition to the disorders listed in Table 21-2, eosinophils may play a role in the pathogenesis of several pulmonary diseases not normally thought of as eosinophilic in origin. Among these is idiopathic pulmonary fibrosis, in which elevated numbers of eosinophils in BAL fluid have in some studies been associated with a poor prognosis.[336] This is consistent with in vitro and animal data demonstrating the ability of eosinophils to promote tissue fibrosis. Another example is cystic fibrosis, in which increased levels of cationic eosinophil granule proteins correlate with worse pulmonary function, presumably due to toxic effects of these proteins on lung cells.[337]

Pharmacologic Modulation of Eosinophils

Corticosteroids have been the mainstay of pharmacotherapy for eosinophilic disorders for many years. Corticosteroids induce apoptosis of eosinophils, both directly and by inhibiting formation of the prosurvival cytokines IL-5, IL-3, and GM-CSF.[255,256,329] This leads to rapid reductions of circulating and tissue eosinophils and clinical improvement in the majority of treated patients. Leukotriene receptor antagonists and the anti-IgE monoclonal antibody omalizumab are two other classes of drugs used to treat asthma and allergic diseases that have been shown to reduce circulating eosinophil counts and cause eosinophil apoptosis.[327,338] Of course, these classes of drugs are not specific for eosinophils, so the degree to which their anti-eosinophil activities contribute to their beneficial effects is uncertain.

More recently, several highly selective anti-eosinophil therapeutics have been developed, tested in clinical trials, and approved for clinical use in the United States. The best studied of these new agents is the anti-IL-5 monoclonal antibody mepolizumab, which is highly effective in reducing circulating eosinophil levels in asthma. Although it did not improve clinical endpoints in mild to moderate asthma,[339] mepolizumab has been shown to reduce exacerbation rates, facilitate corticosteroid tapering, and improve asthma-related quality of life in patients with severe, oral steroid–dependent asthma and increased sputum eosinophils.[331,332,340] As noted earlier, mepolizumab also facilitated oral steroid tapering and reduced flare-ups in randomized trials of patients lymphocytic HES.[334,335] Similarly, mepolizumab increased the rate of remission and facilitated steroid tapering in eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome).[341] Reslizumab,[342,343] another anti-IL-5 monoclonal antibody, and benralizumab,[344] which targets the IL-5 receptor α chain, have benefits similar to mepolizumab and are also approved for treatment of severe eosinophilic asthma. Dupilumab, a monoclonal directed against the common IL-4/IL-13 receptor α chain, also reduced exacerbations and improved pulmonary function and symptom control in severe eosinophilic asthma.[345]

Other eosinophil-selective therapies in clinical development include monoclonal antibodies, antisense oligonucleotides, and small molecule inhibitors targeting CCL11, CCR3, and IL-1.[346] An intriguing anti-eosinophil strategy in early clinical development involves targeting Siglec-8, a sialic acid–binding immunoglobulin-like lectin expressed on the surface of human eosinophils and MCs. Engagement of Siglec-8 with cross-linking antibody or glycan ligands triggers selective apoptosis of eosinophils and inhibits inflammatory mediator synthesis and release by MCs (without affecting their survival), suggesting the possibility that activators of Siglec-8 signaling might be particularly effective therapeutic agents by their ability to target two major cell types that drive allergic respiratory disease.[347,348] Indeed, a monoclonal antibody directed against siglec-8 triggered NK cell–mediated antibody-dependent depletion of asthmatic sputum eosinophils and inhibited activation of MC in human lung tissue.[349] The anti-Siglec-8 monoclonal antibody also depleted tissue eosinophils and improved symptom scores in patients with eosinophilic gastritis and duodenitis.[350]

Ongoing and future investigations involving these novel eosinophil-targeted therapies listed earlier, as well as others yet to be devised, will hopefully lead to safe and even more effective new treatments for eosinophilic respiratory disorders. Such studies will also almost certainly yield new and unexpected insights into the complex mechanisms that eosinophils play in human health and disease.

CHAPTER 22

Antibody-Mediated Lung Defenses and Humoral Immunodeficiency

Homer L. Twigg III

INTRODUCTION

Antibody-mediated, or humoral, immunity is essential for host defense against respiratory pathogens. Defects in humoral immunity are common and frequently underappreciated. From a respiratory perspective, patients with impaired humoral immunity are susceptible to recurrent bacterial sinopulmonary infections and bronchiectasis. Antibody responses are also the principal mechanism behind the efficacy of vaccination against respiratory pathogens. This chapter focuses on our understanding of the normal B cell environment in the lung, generation of appropriate antibody responses after antigenic challenge, disease states associated with impaired lung humoral immunity, and the pulmonary response to vaccination.

OVERVIEW OF B CELL DEVELOPMENT (ONTOGENY)

The primary cell responsible for generating humoral immunity is the B lymphocyte. There are two phases in the development of antibody responses. The first phase is antigen independent and is called lymphopoiesis. As with the generation of other immune cells, the process begins with a multipotent stem cell in the bone marrow that undergoes multiple maturation steps leading to mature but antigen-naïve B lymphocytes (Fig. 22-1) that express IgM and IgD on the cell surface.[1] This process occurs entirely within the bone marrow (or liver during fetal development). Important cytokines in this process include interleukin 7 (IL-7),[2] *ckit*-ligand (stem cell factor),[3] and IL-11.[4] Mature B cells express surface the receptors CD19, CD20, CD21, and CD72.[5,6] CD20 is especially relevant as it is the target of the monoclonal antibody rituximab, which is used to deplete B lymphocytes in B cell lymphoproliferative disorders[7] and autoimmune disorders characterized by the production of pathogenic autoantibodies.[8]

At the completion of lymphopoiesis, IgM-expressing B cells traffic to various lymphoid organs, including lymph nodes in the lung, to await antigenic challenge and enter immunopoiesis.[9,10] Thus, unlike lymphopoiesis, immunopoiesis is antigen dependent. The end result of immunopoiesis is the generation of antibody-secreting plasma cells[1] and long-lived memory B cells, which secrete immunoglobulin only upon re-exposure to antigen.[11] During immunopoiesis class switch, recombination and somatic hypermutation occur resulting in the generation of IgA- and IgG-secreting cells out of IgM precursors, which will be discussed in detail below. Immunopoiesis is most efficient in the presence of antigen-activated T cells, which provide “help” to B cells in the form of cytokines and cell surface activation signals. The latter signal most critical is the interaction between CD40 on B cells and CD40L on activated T cells. The importance of CD40–CD40L in signaling in antibody generation is highlighted by recent efforts to block this interaction in the treatment of various cancers[12] and autoimmune diseases.[13] However, early in B cell development this interaction is crucial, and in the absence of such signaling (e.g., due to genetic mutations in CD40 or CD40L) class switching fails to occur, resulting in the accumulation of IgM-secreting cells and the hyperimmunoglobulin M syndromes, discussed later in this chapter.

IMMUNOGLOBULIN DEVELOPMENT AND STRUCTURE

Below are considered the structure of immunoglobulins, their formation, and immunoglobulin subtypes.

■ Basic Structure

Immunoglobulin (Ig) molecules expressed are made up of two identical protein heavy chains and two identical kappa (κ) or lambda (λ) light chains.[14,15] Immunoglobulin heavy-chain genes reside on chromosome 14 and immunoglobulin light chains are derived from

Figure 22-1 Overview of B cell ontogeny. Lymphopoiesis, occurring in the bone marrow or fetal liver, is an antigen-independent process that begins with a multipotent stem cell and ends with an IgM-expressing immature B cell that will migrate to lymphoid tissues. Immunopoiesis begins with antigen stimulation (hence antigen dependent) and results in antibody-secreting plasma cells and antibody-expressing memory B cells. Class switch recombination leads to the generation of different immunoglobulin subtypes (IgG, IgA, IgE) from activated IgM-expressing B cells. AID, activation-induced cytidine deaminase; BTK, Bruton’s tyrosine kinase; UNG, uracil-N-glycosylase.

either the Igκ-locus on chromosome 2 or the Igλ locus on chromosome 22. Immunoglobulin heavy chains contain both a variable region that will ultimately contribute to antigen binding, and a constant region that binds to cell Fc receptors and complement. Mature immunoglobulin light chains also contain variable and constant regions. Within each variable region there are hypervariable regions, which represent the actual antigen-binding site, and less variable regions, which make up the *framework region*.

The variable domain of the heavy chain is encoded by three sets of genes, the variable (V), diversity (D), and junctional (J) genes, which must be physically rearranged to result in expression of immunoglobulin heavy-chain protein.[16] Similarly, the variable region of the immunoglobulin light-chain protein is encoded by two sets of genes, the V and J genes, which are likewise rearranged to allow transcription of functional protein.[15,16] The rearrangement of DNA to join V, D, and J heavy-chain genes and V and J light-chain genes also results in elimination of unused V, D, and J sequences and noncoding stretches of DNA or introns. The many possible variable regions resulting from these random rearrangements confer a broad range of potential antigen specificities to the mature immunoglobulin molecules.

■ Class Switching

Once immunopoiesis is initiated B cells alter the isotype of antibody that is produced via *isotype switching*.[16,17] This occurs in *switch regions* on immunoglobulin heavy chains through a process called *class switch recombination*. By translocation of the IgM variable region to switch regions adjacent to one of the constant regions coding for IgG, IgA, or IgE, the B cell can maintain antigen specificity and, at the same time, generate different immunoglobulin subtypes with different functional capabilities. Class switch recombination requires an enzyme called activation-induced cytidine deaminase (AID). AID is also critical for *somatic hypermutation*, a process where rapidly proliferating activated B cells have a high rate of point mutations in genes encoding the variable region, leading to production of antibodies with different antigen-binding affinities.[18] This results in a greatly expanded repertoire of B cells expressing surface IgG of different affinities for the triggering antigen. B cells expressing high-affinity antibody on their surface (and thus binding greater amount of antigen) have a survival benefit over B cells coated with weaker affinity to antigen, where less signaling through antigen recognition results in B cell apoptosis. In this way, the antibody response moves toward production of higher affinity and more specific immunoglobulin. The importance of AID is reflected in the development of one of the hyperimmunoglobulin M syndromes in patients with defects in this enzyme.[19] The structure of the various immunoglobulin classes is shown in Fig. 22-2.

Figure 22-2 Basic immunoglobulin structure. Immunoglobulin molecules consist of two identical protein heavy chains and two identical light chains joined by disulfide bonds. Both heavy and light chains contain a constant and a variable region. Within each variable region there are hypervariable regions that represent actual antigen-binding sites. IgM typically exists as a pentamer and IgA as a dimer.

■ Lung Immunoglobulins

In the lung, immunoglobulins constitute the second largest class of proteins present in bronchoalveolar lavage (BAL) fluid after albumin.[20] IgG is the major immunoglobulin in the lower respiratory tract.[21] In contrast, IgA is the most abundant immunoglobulin in secretions from the upper respiratory tract, exceeding the concentration of IgG by a ratio of 2.5:1. Smaller amounts of IgE are consistently found in the BAL fluid of normal subjects.[20]

IgG

IgG is the major circulating immunoglobulin found in the vascular compartment. In normal subjects, the amount of IgG measured in BAL (usually expressed as an immunoglobulin/albumin ratio) is in the same proportion as serum, suggesting that under resting conditions most IgG in the lung represents transudation from the vascular compartment.[20] This is further supported by the relatively small size of IgG (150,000 D). There are four IgG subclasses found in BAL fluid in approximately the same proportions as found in serum. IgG1 represents approximately 60% to 70% of the IgG present in BAL fluid, IgG2 20% to 25%, and IgG3 and IgG4 are present only in small amounts (<5%).[21] Responses to protein antigens predominantly reside in the IgG1 and IgG3 subclasses, while polysaccharide antigens predominantly give rise to IgG2 antibodies.[22,23]

The major function of IgG is to opsonize pathogens and target them for clearance either through uptake by phagocytic cells or by fixing complement. In this regard, IgG1 and IgG3 fix complement more avidly than IgG2.[24] Antibody also binds to Fc receptors on phagocytic cells to facilitate uptake. The three primary Fc receptors are FcRI, FcRII, and FcRIII. IgG1 and IgG3 bind FcRIII receptors on phagocytic cells equally well and more potently than IgG2.[25] IgG1 binds to the other Fc receptors more avidly than the other IgG subclasses. Binding of antigen–antibody complexes to Fc receptors is potentially a double-edged sword. On the one hand, not only is uptake of opsonized pathogens through Fc receptors more efficient, so is the intracellular digestion of organisms in phagolysosomes. For example, uptake of opsonized *Mycobacterium tuberculosis* through the Fc receptor results in intracellular killing of the organism, while uptake through other receptors (e.g., the mannose receptor) allows the organism to escape digestion.[26] On the other hand, uptake of opsonized pathogens through Fc receptors represents an "inflammatory clearance" mechanism that is associated with release of potentially harmful inflammatory mediators into the lung environment.[27]

IgA

In contrast to IgG, IgA is likely locally produced based on an elevated IgA/albumin ratio in BAL compared with serum.[28] IgA can exist as monomeric and polymeric proteins. The latter is usually found as dimeric IgA, characterized by two monomers connected by a J chain.[29] Most IgA in the lung is in dimeric form, with features of secretory IgA (sIgA) characterized by the presence of a J chain and secretory component (SC).[30] The large size of dimeric IgA (385,000 Da) also argues against simple transudation of IgA from the vascular compartment into the lung. Finally, the presence of secretory component in BAL is another argument for the local production of IgA in the lung.[31]

IgA has two subclasses: IgA1 and IgA2.[29] IgA1 constitutes nearly 80% of serum IgA. In contrast, IgA2 appears to be important in mucosal immunity and nearly half of the IgA present in secretions is IgA2. IgA exerts its protective effect through three mechanisms.[32]

First, it serves as an immunologic barrier, inhibiting binding of organisms to mucosal surfaces. Second, the normal movement of IgA from the basilar to apical region of epithelial cells suggests that it may be effective in neutralizing intracellular pathogens. Finally, pathogens bound to IgA may be taken up by airway macrophages through the phagocytic process.

IgM

IgM is present only in very low amounts in respiratory secretions from normal subjects.[20] It exists as a pentamer, and the resulting very large size (900,000 Da) limits transudation into the lung under normal conditions. Nevertheless, IgM in BAL is greater than would be expected for simple diffusion, suggesting some local production.[33] Furthermore, in some disorders characterized by lower respiratory tract inflammation, IgM can be detected. However, in this setting, it is almost certainly largely derived from serum transudation as part of the inflammatory process.

IgE

Under normal conditions, the amount of IgE in BAL is lower than IgG, IgA, or IgM.[33] When present, the IgE/albumin ratio suggests local production.[33] IgE-antigen complexes bind the high-affinity receptor for IgE (FcRI) on mast cells, basophils, and eosinophils leading to immediate hypersensitivity responses.[34,35] IgE is important for host defense against parasites mediated by eosinophils.[36] However, in developed countries, the main role of IgE in pulmonary immunity is in the pathogenesis of allergic and asthmatic disease.[37,38] The severity of disease is correlated with serum IgE in asthma and allergic patients. The importance of this molecule in the pathogenesis of asthma has led to the development of anti-IgE antibodies for patients with resistant IgE-mediated disease.[39] Interestingly, when IgE binds to the low-affinity FcRII receptor, it inhibits IgE synthesis and reduces inflammation.[40] Thus, IgE may also have a role in downregulating the immune response.

■ Cellular Interactions Leading to Antibody Secreting Cells

Important considerations in development of antibody secreting cells are discussed below.

■ B1 and B2 Cells

B lymphocytes constitute 1% to 10% of the lung lymphocyte population and can be separated into two main classes. Plasma cells constitutively secrete IgG and other immunoglobulin subclasses.[1,11] In contrast, memory B cells produce immunoglobulin only in response to re-exposure to particular antigens.[11] B cells can be further classified into B1 and B2 cells, although recent studies suggest there is plasticity between the two subtypes.[41] B1 cells were first described in the gastrointestinal tract. These cells are IgM+, CD5+ cells that do not require T cell help for development.[42] In the lamina propria, B1 cells undergo class switching to an IgA secretory cell. B1 cells home to peritoneal and pleural cavities, respond to common bacterial antigens, and are felt to be very important in the production of IgM and IgA against bacterial pathogens at mucosal sites.[43] As such, they are thought to be important in innate immunity against conserved bacterial antigens. Because of their autonomous ability to secrete antibody, they are also felt to contribute to autoimmune diseases.[44] These cells are difficult to demonstrate in normal lung. As stated above, T cells are not necessary for B1 cells to produce antibody, although the presence of T cells appears to augment the immune response.[45–47]

In contrast to B1 cells, B2 cells require T cell help, mainly through secretion of the cytokines IL-4, IL-6, IL-7, and IL-10, along with interferons,[48] as well as ligation between CD40 on B cells and CD40L on T cells.[49] T cell–dependent antibody responses begin with uptake of antigen by accessory cells (AC) and presentation to T cells. AC function can be carried out by mononuclear phagocytes (monocytes, macrophages) or dendritic cells. Submucosal dendritic cells are likely the principal accessory cell in the lung.[50] B cells themselves can also serve as the accessory cell leading to T cell activation.[51] B cells in the lung express surface IgG and IgM. Crosslinking of surface IgG or IgM by antigen results in partial activation of B cells leading to expression of IL-2 receptors and MHC class II molecules,[1] which allows them to serve as accessory cells in T cell activation. With appropriate T cell help, activated B cells eventually differentiate into short-lived antibody-producing plasma cells or memory B cells, the latter being characterized by the co-expression of CD20 and CD27.[52] Other surface markers indicating B cell activation and differentiation include CD69, CD80, and CD86.[1] The latter two interact with CD28 and CTLA4 on T cells, respectively, thereby enhancing proliferation of helper T cells. Activation results in production of CD38+ CD138+ plasma cells, which secrete IgM (primary response) or other immunoglobulin isotypes (secondary immune responses).[53] IL-21 is critically important in the terminal differentiation and expansion of plasma cells.[54]

■ Cognate versus Noncognate Responses

Activated T cells can prove cognate and noncognate B cell help. Cognate B cell help is antigen- and MHC-restricted and occurs after helper T cells have been activated through T cell receptor (TCR)-MHC class II/antigen complex mechanisms. It was initially thought that B cells were the obligate accessory cells for cognate responses since B cell–T cell contact was occurring through MHC class II/antigen complexes on activated B cells and the TCR on T cells. In contrast, when T cells are stimulated by accessory cells other than B cells or activated in an accessory cell–independent manner (e.g., with immobilized anti-CD3), T cells can induce immunoglobulin production in many B cells in a non-MHC- or antigen (noncognate)-restricted manner. This latter phenomenon results in stimulation of both antigen specific as well as "bystander" B cells, leading to a polyclonal antibody response. Subsequent work has shown that this bystander response is present when T cells providing B cell help are highly activated and/or differentiated and is dependent on both B and T cell contact through CD40–CD40L receptor interactions as well as cytokine secretion from activated T cells.[55] Additional work has shown that the bystander effect can also be mediated by transfer of the B cell receptor from antigen-stimulated B cells to neighboring B cells, thereby greatly increasing the number of antigen-specific B cells available to stimulate T cells to provide help.[56]

■ Cytokine Secretion

Resting T cells provide poor B cell help. T cells that have been stimulated by antigen can be loosely divided into Th1 (T helper 1) and Th2 (T helper 2) cells based on the cytokine profile they secrete.[57] Th1 cells secrete predominantly interferon γ (IFN-γ) and IL-2 and are involved primarily in cellular immunity. Th2 cells secrete IL-4, IL-5, and IL-10 and drive humoral immunity. Th2 cells that provide B cell help are called "effector" cells. Signals from T cells to B cells are in two forms: direct cell-to-cell contact and cytokine secretion. While direct B cell–T cell contact is required for induction of antibody production, both Th1 and Th2 cell membranes can provide this signal.[58] What differentiates these two T cell populations is the cytokine profile they secrete. In particular, IL-4 seems to be an early competence factor that increases the number of B cells responsive to T cell help.[58,59] In contrast, IL-6 is a late factor that promotes continued B cell proliferation and immunoglobulin secretion.[59] IFN-γ downregulates most immunoglobulin secretion.[60] Thus, Th2 cells secrete a more favorable cytokine pattern for immunoglobulin production. The one exception is IgG2, which is dependent on IFN-γ secretion.[60]

Specific B Cell and T Cell Receptor Interactions and Downregulation of B Cell Responses

Tight regulation of antibody production and secretion is necessary to turn off the response when it is no longer needed and to prevent production of unwanted autoantibodies. This control is mediated through a combination of signaling pathways between T cells and B cells (Fig. 22-3). CD40L is an activation-induced molecule on CD4 T cells that delivers signals to B cells through its counterreceptor CD40, which is constitutively expressed on B cells. Highly activated T cells express increased CD40L. CD40 on B cells in turn downregulates CD40L on activated T cells.[61] These cells are subsequently unable to stimulate resting B cells. Thus, this may represent an attempt to downregulate noncognate immunoglobulin production. However, CD40 ligation is still critically important for cognate interactions. Crosslinking of surface immunoglobulin on B cells results in apoptosis of the B cell unless simultaneous binding of CD40 by CD40L occurs.[62] Interestingly, CD40 binding alone induces Fas expression on B cells, an effect that is not inhibited even in the presence of B cell tropic factors such as IL-2, IL-4, and IL-10.[63] Thus, ligation of CD40 acts to co-stimulate B cells that have been activated by binding of specific antigen while simultaneously increasing sensitivity to apoptosis in B cells not crosslinked by antigen. This drives an antigen-specific antibody response.[62]

The role of Fas/FasL interactions in modulating immune responses is well established. Activation of T cells upregulates expression of both Fas and FasL. This is seen as a mechanism to control chronic T cell activation.[64] Fas/FasL interactions are also important in modulating B cell responses.[65] As stated above, B cells stimulated through CD40 increase expression of Fas. Thus, these cells are susceptible to apoptosis mediated by FasL expressed by activated T cells. B cell apoptosis induced by FasL is blocked if there is simultaneous crosslinking of surface immunoglobulin by antigen, thereby preserving secretion of protective antibody in the presence of persistent pathogen exposure.

Figure 22-3 Interaction between T cells and B cells during the generation of a humoral response. Multiple signals occur between T cells and B cells. Depending on the presence or absence of crosslinking of surface immunoglobulin on B cells, T cells can either promote B cell growth or induce apoptosis.

Pulmonary Antibody Production in Response to Antigen Exposure

Pulmonary immunity to pathogens can be divided into innate and acquired responses. Most pathogens gaining access to the alveolar space are handled by phagocytosis by alveolar macrophages, the principal form of innate immunity. If phagocytosis of pathogens occurs in the absence of opsonizing antibody, this usually results in "non-inflammatory clearance," with minimal release of inflammatory mediators and preservation of lung structure and function.[66] If phagocytosis is overwhelmed, a specific acquired immune response occurs. This involves the interaction of B and T lymphocytes to produce an antigen-specific cellular and humoral immune response. In the lung, the acquired response has three distinct phases (Fig. 22-4)—afferent antigen processing and transport to regional lymph nodes,[67] presentation to naïve lymphocytes, and efferent migration of activated T lymphocytes and mature B cells back to

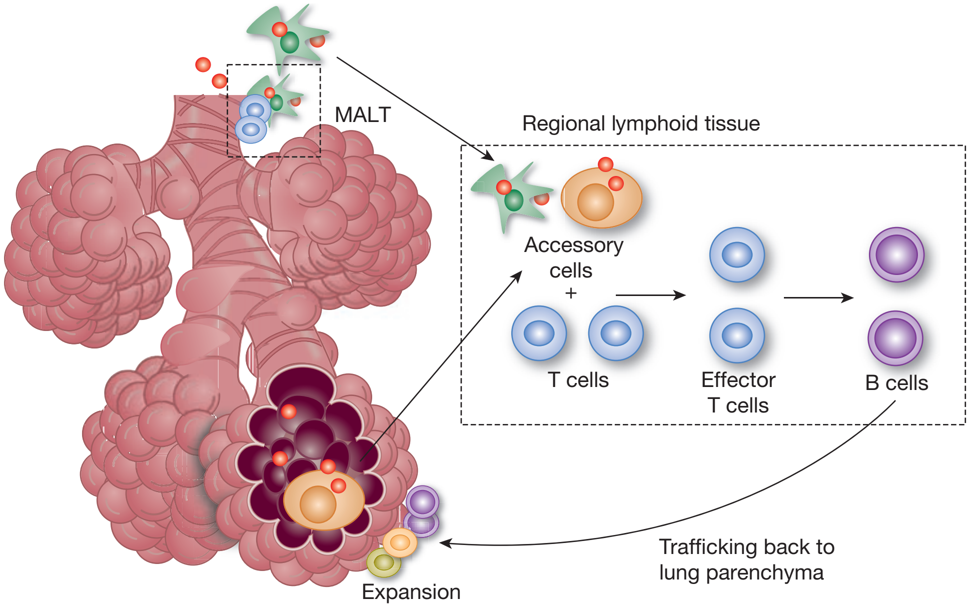

Figure 22-4 Pathway for generation of antigen-specific immune responses in the lung. Foreign antigen is taken up by antigen-presenting cells and transported to regional lymph nodes where the primary cellular and humoral immune response is generated. Effector cells then traffic back to the lung to the site of initial antigen challenge. B cells will become antibody-secreting plasma cells, while others will become memory B cells. This circuit is significantly shorter in the presence of mucosal-associated lymphoid tissue (MALT).

the site of initial antigenic challenge in the lung.[68] This results in the presence of antigen-specific immunoglobulin in the lung lining fluid and consequent increased effectiveness of professional phagocytes such as alveolar macrophages and neutrophils.[69]

This general pathway is similar for IgG and IgA production, although the length of the "circuit" is likely much less for IgA. Rather than having the antigen travel to regional lymph nodes, in mucosal immunity, IgA can be generated in specialized lymphoid tissue just beneath the mucosal surface, called mucosal-associated lymphoid tissue (MALT). This suggests that IgA-secreting plasma cells are produced locally, and IgA can readily diffuse back into the airspaces. Such submucosal lymphoid tissue in the upper airway, called nasal-associated lymphoid tissue (NALT), is seen in most animal species, including humans.[70] In contrast, in the lower respiratory tract bronchus-associated lymphoid tissue, or BALT, is readily demonstrable in mice[70] but has been more difficult to find in normal human airways.[71] Studies claiming that humans have BALT have generally been in subjects with an inflammatory pulmonary process.[72] To address these conflicting studies, the concept of inducible bronchus-associated lymphoid tissue, or iBALT, has been introduced. In mice, iBALT is clearly found in multiple infection models, including those lacking secondary lymphoid tissues (spleen, lymph nodes),[73] and is associated with robust B cell responses.[74] Similar pulmonary inflammatory conditions can induce iBALT in humans.[75] Thus, collections of antigen-presenting cells, B cells, and T cells in the submucosa, which are thought to collectively represent BALT, may be readily detectable only during times of antigenic challenge.

Once antibody producing B cells are formed in secondary lymphoid tissue or MALT, they must traffic back to the original point of entry of the pathogen. This trafficking of lymphocytes back to mucosal sites has been intensely studied, giving rise to a four-step model. The first step is tethering. L-selectin on lymphocytes interacts with addressins on endothelial cells to slow down the movement of lymphocytes through capillaries. In NALT, the responsible endothelial receptor is PNAd,[76] while in the lung, adhesion is mediated by ICAM-1.[77] Tethering leads to lymphocyte activation mediated by chemokines and their receptors and subsequent firm adhesion to the endothelium. The latter is mediated by LFA-1 binding to ICAM-1 and $\alpha_4\beta_7$ integrin binding to MADCAM-1.[78] Finally, diapedesis through the mucosa occurs, a process that probably involves all the above receptor–counter receptor interactions.

The end result of this process is the accumulation of antibody-secreting plasma cells at the site of initial challenge. Once the invading pathogen has been cleared, plasma cells disappear and are replaced by memory B cells. The great majority of B cells in the normal lung are mature memory B cells. This mirrors the predominance of memory T cells in the lung,[79] suggesting that the lung is primed to respond quickly to antigenic challenges. IgG-, IgM-, and IgA-secreting B cells are present in normal subjects; however, poor correlations exist between the numbers of Ig-producing BAL cells and the levels of Ig in BAL fluids.[20,80] In BAL fluid from nonsmokers IgG is present in the same proportion as in serum, leading to speculation that most IgG enters via transudation from the plasma compartments.[20,81] These two observations fit in well with the primary presence of memory B cells in the lung, suggesting that under resting conditions very little local antibody is made. Only after antigenic challenge is local production increased. In support of this is the finding of increased ratios of specific to total antibody in BAL fluid after pneumococcal infection, suggesting that local antibody production can be increased after relevant exposures.[82]

As will be discussed below, immunoglobulin deficiencies primarily lead to an increase in bacterial infections, including pneumonia. IgG seems to be particularly important in host defense against bacterial pneumonia. However, there appears to be an increased role for IgA protection in viral infections, likely due to the fact they are usually initially encountered at mucosal surfaces. Very recent studies exploring the pulmonary immune response to the SARS-CoV-2 demonstrate that both IgG and IgA are generated during infection and can be found in bronchoalveolar lavage and saliva in addition to serum.[83] Furthermore, IgA possessed more viral neutralizing capacity than IgG and persisted longer in saliva.[83] Similar observations have been observed in response to influenza infection,[84] suggesting that IgA is a critical component of host defense against viral pneumonia.

DISORDERS OF HUMORAL IMMUNITY AND LUNG DISEASE

In general, defects in humoral immunity result in an increased susceptibility to bacterial infections, including recurrent sinusitis, bronchitis, pneumonia, otitis media, and even meningitis. In particular, patients are susceptible to infection with encapsulated organisms, such as *Hemophilus influenzae*, *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Neisseria* species. Chronic diseases such as bronchiectasis and obstructive lung disease can result from recurrent infections. Antibody defects can be either quantitative (an absolute decrease or loss of antibody) or qualitative (poor antigenic specificity and or poor opsonic function). In addition, the presence of antibodies against host antigens can lead to autoimmune lung disease. Figure 22-5 shows some of the known molecular defects causing immunoglobulin deficiency. The cause of most of the selective immunoglobulin deficiencies described below is unknown.

■ Quantitative Defects

Isolated *IgA deficiency* is the most common primary immunodeficiency in humans, occurring in roughly 1 in 500 individuals.[85,86] The presence of selective IgA deficiency is defined by a serum IgA level of less than 7 mg/dL and normal levels of other immunoglobulins. Asthma, IgE-mediated allergic disease, and autoimmune diseases are more common in patients with IgA deficiency.[87,88] Potential explanations for these observations include the inability to clear allergic antigens[89] and dysbiosis of the gut and lung microbiome.[90,91] Only about a third of patients with IgA deficiency develop recurrent sinus, pulmonary, and gastrointestinal tract infections, usually with encapsulated bacteria. In the absence of an associated IgG subclass deficiency the development of structural lung disease is rare. These patients almost never require immunoglobulin replacement therapy. However, the coexistence of IgA and IgG subclass deficiency is extremely important to document since the latter may require immunoglobulin infusions. IgA-deficient patients are at increased risk for anaphylactic reactions after blood product infusions, including immunoglobulin preparations, because of the presence of IgG anti-IgA antibodies in up to 60% of individuals.[92] As such, when the decision is made to give immunoglobulin infusions to an IgG-deficient patient with a coexisting low IgA level, immunoglobulin preparations low in IgA must be used.

In contrast to IgA deficiency, patients with *IgG subclass deficiencies* frequently exhibit recurrent sinus and respiratory tract infections with encapsulated organisms regardless of whether it is associated with IgA deficiency.[93] Recurrent infections in IgG subclass deficiency can lead to chronic bronchiectasis, and assessment of immunoglobulin deficiency should be part of the standard evaluation of patients with unexplained recurrent infections with destructive lung disease. Decreased IgG2 is the most common IgG subclass deficiency and results primarily in an impaired ability to respond to polysaccharides.[22] As such, their response to the standard polysaccharide pneumococcal vaccine is poor, and they have an increased susceptibility to infections with encapsulated bacteria.[94] When IgG subclass deficiency is combined with IgA deficiency, the resultant lung disease is more severe than with either deficiency alone.

More severe disease occurs when there are multiple immunoglobulin defects. The most common immunodeficiency in this group is *common variable immunodeficiency (CVID).* Present in 1 in 25,000 individuals, this disease is characterized by hypogammaglobulinemia,

decreased antigen-specific antibody responses, and recurrent sinopulmonary infections, frequently leading to chronic lung disease.[95] IgG levels are usually below 300 mg/dL and are accompanied by low IgA and IgM levels as well. Specific antibody responses to common antigens such as tetanus toxoid and pneumococcus are usually very low. Cellular immune defects, primarily lymphopenia with a normal or decreased CD4:CD8 ratio, also may be present. Thus, patients may present with infections typically associated with T cell defects (fungi, mycobacteria) in addition to infections caused by encapsulated bacteria. Proliferation of B cells and T cells in response to strong mitogens is impaired as well. While the cause of most cases of CVID is unknown, some patients have been found to have either intrinsic B cell genetic defects or defects affecting the ability of T cells to provide B cell help,[95,96] resulting in failure of B cells to class switch or terminally differentiate. Defects in immunity also impair immunosurveillance, leading to an increased incidence of autoimmune disease and malignancies in patients with CVID.[97,98]

Patients with *X-linked agammaglobulinemia (Bruton's agammaglobulinemia)* demonstrate a generalized defect in the ability to make all immunoglobulin classes. This is due to a deficiency of Bruton's tyrosine kinase (BTK), which is essential for early lymphopoiesis.[99] These individuals present in early childhood with recurrent middle ear, sinus, pulmonary, joint, bone, and CNS infections. They almost always develop chronic lung disease including bronchiectasis, pulmonary fibrosis, and pulmonary hypertension.[100,101] IgG levels are below 200 mg/dL and the other Ig subclasses may be absent. In contrast to patients with CVID, lymphoid tissue is hypoplastic in these patients.

Hyperimmunoglobulin M syndrome refers to several diseases characterized by low concentrations of IgG, IgA, and IgE, and a normal or elevated IgM level.[102] As might be expected based on our understanding of normal B cell development, these syndromes result from failure of IgM-secreting B cells to undergo class switching. The most common disorder is X-linked hyperimmunoglobulin M syndrome, which arises from a deficiency in the important T cell co-stimulatory molecule CD40L.[103] Deficiency in the B cell CD40 molecule also has been described, although this is rare.[104] Patients with either of these disorders have severely impaired T cell–dependent antibody production. Other hyperimmunoglobulin M disorders are caused by genetic mutations in the enzymes required for class switching, such as activation-induced cytidine deaminase[105] and uracil nucleoside glycosylase.[106]

Immunoglobulin replacement therapy can prevent recurrent infection and ameliorate some of the long-term sequelae of IgG deficiency.[107,108] Replacement therapy has also been reported to reduce the incidence of malignancies in patients with CVID.[98] However, it is important to base treatment decisions on the inability to make specific antibody, not just on an isolated low IgG (or IgG subclass) level. When immunoglobulin deficiency is suspected, total IgG, IgA, IgM, and IgG subclass concentrations are checked. A lymphocyte phenotype panel should also be obtained to look for low T and B cell numbers. If low antibody titers are detected, then one should measure common specific antibody titers. Usually, tetanus toxoid and pneumococcal antibody titers are assessed because this assesses both the ability to respond to protein (tetanus) and polysaccharide (pneumococcal) antigens. If specific antibody titers are low the patient should be given the tetanus or pneumococcal vaccine and repeat antibody titers obtained 4 weeks later. Failure to increase antibody titers into a "protective" range is indicative of immunoglobulin deficiency and warrants consideration of immunoglobulin replacement therapy. There are several immunoglobulin preparations available. As mentioned above, if IgA deficiency is present, a preparation that contains very low IgA should be used to minimize the risk of anaphylaxis.[92] The typical dose of immunoglobulin is 400 mg/kg given once a month, with a goal trough immunoglobulin immediately before the next infusion of 500 mg/dL.

Qualitative Defects

Once antibody is produced in the lung, it must be effective in promoting clearance of the offending pathogen. Only having a vigorous antibody response is insufficient. There are several diseases characterized by poor functioning antibody.

Specific antibody deficiency (SAD) is characterized by poor antibody responses to polysaccharide antigens despite normal IgG, IgG subclass, IgM, and IgA concentrations.[109] While many of the primary immunodeficiency diseases described above are associated with poor responses to polysaccharide antigens, SAD should be reserved for patients with only this specific defect. SAD is one of the most common immunodeficiencies, occurring in 5% to 10% of older children and adults presenting with recurrent sinopulmonary infections.[110,111] As with other immunoglobulin deficiencies, these patients also have an increased incidence of atopic disease. Since SAD is a diagnosis of exclusion, normal IgG, IgG subclass, IgM, and IgA levels must be demonstrated. To demonstrate polysaccharide unresponsiveness, baseline pneumococcal titers are measured and then the 23-valent polysaccharide pneumococcal vaccine is administered.[112] Four weeks later pneumococcal titers are repeated. An appropriate response is indicated by an antibody titer of 1.3 μg/mL or greater in 70% of the serotypes tested.[112] Some patients have an appropriate response to vaccination, but this is followed by a rapid loss of antibody titers over 6 months. These patients fall within the spectrum of patients with SAD. One of the main reasons for establishing the diagnosis of SAD versus other immunodeficiencies is the differences in treatment. Patients with SAD should be administered the 13-valent conjugated pneumococcal vaccine, which is more immunogenic due to the presence of a protein carrier attached to polysaccharide antigens, which acts as a hapten.[86,113] Prophylactic antibiotics are also frequently used in patients who have recurrent respiratory infections.[114] Unlike in more severe humoral immunodeficiencies, immunoglobulin replacement therapy is needed only in a minority of patients with SAD and should be reserved for those who fail vaccination strategies and prophylactic antibiotics.[109]

While *HIV infection* is most notably characterized by profound defects in cell-mediated immunity, antibody defects also are present. In fact, the occurrence of recurrent bacterial pneumonia remains an AIDS-defining illness in children and adults.[115] Pneumococcal infections are especially problematic in the HIV-infected population,[116] suggesting these patients have an especially profound defect in the ability to respond to polysaccharide antigens. Indeed, studies suggest that HIV-infected subjects have a relative defect in IgG2[117] and that this may be due to impaired T cell help toward IgG2 antibody-secreting cells.[118] The result is an antibody repertoire that is skewed towards pneumococcal proteins rather than polysaccharides.[119] These studies have been primarily performed on blood and various mucosal sites. Studies from the lower respiratory tract are more limited and demonstrate that there is an increased amount of total and pneumococcal-specific antibody in the alveolar space.[82,120] For example, in HIV-infected Malawians, a population with a high incidence of invasive pneumococcal infection, BAL contains four times the amount of pneumococcal-specific IgG compared with non-HIV-infected subjects. Capsule-specific IgG levels were highest in a group of HIV infected patients with recent invasive pneumococcal disease, suggesting that despite polyclonal IgG responses in HIV-infected adults, appropriate responses to infection also were present.[82] However, the ability of highly purified BAL IgG from HIV-infected subjects to bind pneumococci is impaired compared with BAL IgG from non-HIV-infected subjects.[121] This parallels the work of other investigators who have demonstrated impaired immunoglobulin opsonic function in HIV infected subjects, including activity against pneumococcus.[122,123] Thus, HIV-infected subjects appear to have dysfunctional pneumococcal antibody in the alveolar space. These findings highlight the fact that better correlates are needed for assessing the host response to natural infection or vaccination besides simple measurement of antibody concentrations.[124]

Pulmonary Disease Associated with Autoantibodies

There are many well-described lung diseases associated with the presence of autoantibodies. Classically these have been described in patients with vasculitic processes such as Goodpasture's syndrome, granulomatosis with polyangiitis, and various connective tissue diseases. A discussion of these disorders is beyond the scope of this chapter. However, a great deal of interest is now turning toward the potential role of autoantibodies in some of the more commonly encountered lung diseases.

Chronic obstructive pulmonary disease (COPD) is increasingly being thought of as an autoimmune disease.[125] Multiple reports demonstrate increased evidence of B cell activation in patients with emphysema.[126–128] While early reports of increased anti-elastin antibodies in patients with COPD[129] have not been uniformly supported,[130,131] investigations continue to demonstrate increased general autoantibodies[132] as well as more specific antibodies against collagen V,[131] cytokeratin,[133] and epithelial and endothelial antigens.[134,135] Furthermore, lymphoid follicles consisting of B cells and follicular dendritic cells with adjacent T cells are present in the parenchyma and in bronchial walls of patients with emphysema, suggesting that at least some these antibodies may be locally produced.[136] This is further supported by detailed studies demonstrating that the B cells in these aggregates have a limited (oligoclonal) repertoire.[136] That these autoantibodies may be pathogenic is suggested by the presence of immune complex and C3 deposition in the lungs of patients with emphysema[134] and strong relationships between evidence of B cell activation and the severity of radiographic emphysema.[128] In animal models, smoking is able to induce autoantibodies against extracellular matrix proteins in mice,[137] and adoptive transfer of anti-endothelial antibodies can cause emphysema in rats.[138] This discussion would suggest immunosuppressive medications may be effective in COPD. Indeed, systemic and inhaled corticosteroids result in decreased lymphoid aggregates in the lungs of humans with COPD.[139] Trials are currently underway examining whether anti–B cell therapies have a role in slowing the progression of COPD.[140] Whether reduction in lung B cell immunity is ultimately helpful or harmful will depend on the balance between secretion of destructive autoantibodies or protective antibodies against microbes that have colonized the airway of these patients.

Another lung disease in which autoantibodies may contribute to pathogenesis is *pulmonary fibrosis*. The current paradigm for the pathogenesis of pulmonary fibrosis starts with lung epithelial and or microvascular injury leading to an exaggerated inflammatory and fibrotic response. While extensive literature exists on the inflammatory and fibrotic response, much less is known about the inciting event. In pulmonary fibrosis associated with connective tissue disease, numerous autoantibodies have been described and in patients presenting with fibrotic lung disease, screening should include testing for antinuclear antibodies (ANA is nonspecific; but, if positive, should prompt search for systemic lupus erythematosus, mixed connective tissue disease, systemic sclerosis, and CREST syndrome), anti-Jo-1 (inflammatory myopathies and anti-synthetase syndrome), SSA and SSB (Sjögren's Syndrome), rheumatoid factor and cyclic citrullinated peptide antibodies (rheumatoid arthritis), and antineutrophil cytoplasmic antibodies (microscopic polyangiitis and other ANCA-associated vasculitis).[141] Many of these antibodies are also found in patients with idiopathic pulmonary fibrosis (IPF) but without overt signs of autoimmune disease,[142] but whether they are pathogenic is not known. Antibodies to alveolar epithelial cells and components or their tight adhesion junctions have been found in patients with IPF and correlate with disease severity.[143,144] More recently, antibodies to modified proteins (citrullinated, acetylated,

AL GRAWANY

carbamylated) have been found in patients with IPF and rheumatoid arthritis associated pulmonary fibrosis,[145–147] suggesting that inflammation-induced protein damage may lead to autoimmunity capable of perpetuating the fibrotic response. These same considerations have led to questions of whether the presence of autoantibodies in pulmonary fibrosis is causative or just an epiphenomenon.[148]

Dysregulated humoral immunity also plays a role in *lung transplant rejection.*[149] B cells are a prominent finding in areas of the lung demonstrating obliterative bronchiolitis, the pathologic hallmark of lung rejection.[150] Furthermore, recent work has demonstrated that blocking the development of B cell lymphoid follicles can prevent lung transplant rejection in a murine model.[151] Like most cases of organ rejection, the classic response is felt to be donor-specific antibodies against donor HLA antigens.[152] However, there is also ample evidence that autoantibodies against collagen V and K-alpha 1 tubulin also play an important role, especially in chronic rejection.[153] In fact, there is increased collagen V expression in obliterative bronchiolitis lesions and the presence of collagen V antibodies in the lungs of patients who had lung transplant rejection.[154] Furthermore, the presence of circulating anti–collagen V antibody predicts primary graft dysfunction after transplant.[155] That autoantibodies may have a pathogenic role in lung transplant rejection is further supported by studies demonstrating that anti–B cell targeted therapies such as rituximab or intravenous immunoglobulin therapy reduce the concentration of the autoantibody and reduce the severity of rejection.[156]

PULMONARY ANTIBODY RESPONSES TO VACCINATION

The pulmonary antibody response to a variety of vaccinations, including pneumococcal and influenza vaccinations, is an important clinical consideration, as discussed below.

■ Systemic versus Mucosal Vaccination

Vaccination against pulmonary pathogens is a common and effective practice against many diseases. However, mechanisms behind their effectiveness are not always clear. Both IgG and IgA have a role in protection after vaccination, providing systemic and mucosal protection, respectively. Mucosal immunity is especially important for pulmonary pathogens,[157] where the mucosal barrier needs to be breached to cause disease. The presence of pathogen-specific IgA should decrease colonization of the respiratory tract by limiting attachment to respiratory epithelium. Since airway colonization is usually the first step in the development of bacterial or viral pneumonia, decreased colonization should lead to a decreased incidence of pneumonia. When pathogens manage to reach the alveolar space, IgG takes on a greater role as an opsonin in the phagocytosis of organisms. Thus, the most effective immunity against infections should involve both IgG and IgA responses. Nonetheless, the vaccine delivery mechanism impacts the type of immune response generated. In general, systemic administration of an antigen results in the generation of circulating IgG, some of which will diffuse into the epithelial lining fluid. In contrast, mucosal antigenic challenge results in a more vigorous IgA response locally at the site of challenge.[157] Whether systemic immunization can induce effective mucosal immunity is controversial and an intense area of study.[158] While there is no question systemic vaccination can ameliorate pulmonary disease as discussed below, there are two factors that theoretically favor attempts to induce mucosal immunity. First, mucosal immunity can be induced through exposure of vaccines to mucosal surfaces and thus alleviate the need for needles, thereby improving tolerance and acceptability.[159] Second, by preventing the initial binding of pathogens to mucosal surfaces, mucosal immunity can actually prevent disease rather than just decrease its severity.[160] In fact, vaccination efforts to eliminate disease have generally used mucosal approaches, the eradication of polio and smallpox being prime examples.[161,162]

Despite the recognition that local antibody may be important in pulmonary host defense, there is remarkably little information on humoral responses in the respiratory tract after systemic immunization, the standard approach to most vaccine strategies. In a mouse model of mucosal immunity against *Mycoplasma pulmonis*, it has been demonstrated that the site of antigen deposition greatly influences the antibody response and subsequent protective immunity.[163] Intranasal challenge resulted in an increase in IgA antibody–forming cells in the nasal submucosa and an increase in mycoplasma-specific IgA in nasal washes. Low numbers of IgA antibody–forming cells and IgA concentrations were seen in the lung after isolated nasal challenge, but were increased significantly if animals received both nasal and pulmonary immunization. Both nasal and nasal-pulmonary vaccine exposures resulted in equivalent antigen-specific IgA and IgG in the systemic circulation. Both forms of immunization also significantly reduced the ability of mycoplasma to colonize the nasal passages after experimental exposure to a mycoplasma inoculum. However, animals receiving nasal-pulmonary immunization had significantly fewer organisms in the lungs compared with animals that received only nasal immunization. Since serum mycoplasma-specific IgA and IgG were similar after both types of immunization, this suggests that circulating antibody is less effective in protection against pulmonary pathogens compared to locally produced antibody.

In another animal immunization model against a different pulmonary pathogen, *Moraxella catarrhalis*, the site of specific antibody production and protection after intranasal and subcutaneous challenge was examined.[164] Intranasal administration of *M. catarrhalis* surface proteins resulted in antigen-specific IgA and IgG in both nasal washes and BAL. IgA concentrations far exceeded IgG concentrations in both sites. IgA was significantly higher in BAL and nasal washes than in serum, whereas IgG was higher in serum than both mucosal sites. Immunization was associated with a marked increase in bacterial clearance after intranasal challenge with live *M. catarrhalis* organisms. As might be predicted, subcutaneous administration of the same vaccine resulted in production of far greater antigen-specific IgG compared to IgA, especially in the lung, where *Moraxella*-specific IgG in BAL was nearly 20 times greater than that found in nasal washes. Subcutaneous vaccination induced a marked systemic IgG response, but virtually no antigen-specific IgA in serum, BAL, or nasal washes. Interestingly, despite the brisk systemic and pulmonary IgG response after subcutaneous immunization, intranasal immunization promoted significantly greater bacterial clearance after intranasal challenge with the organisms. These data further support the general premise that while systemic vaccination results in antigen-specific IgG that may passively diffuse into the epithelial lining fluid in the lung, better protection will be afforded if local IgA immune responses also are induced.

The effect of the intranasal and intramuscular polysaccharide pneumococcal vaccine has also been studied in a mouse model.[165] Intranasal vaccination, when accompanied by IL-12 administration (which increases IFN-γ production), resulted in increased serum IgG2a anti-pneumococcal antibody, consistent with the known stimulatory effect of IFN-γ on IgG2a production.[60] This regimen also resulted in increased pneumococcal-specific IgA in BAL fluid. The serum antibody response was functional in opsonophagocytosis assays. Interestingly, intramuscular vaccination afforded more protection against subsequent intraperitoneal pneumococcal challenge compared with intranasal vaccination. In contrast, intranasal vaccination was more effective in reducing nasopharyngeal colonization after nasal challenge of the organism compared with intramuscular vaccination, despite the higher serum IgG response after the latter. Finally, using IgA knockout mice, these investigators demonstrated that IgA was responsible for reducing pneumococcal colonization after vaccination and intranasal challenge.[165] These early findings using the pneumococcal polysaccharide vaccine have been confirmed more recently by two studies using pneumococcal surface protein A vaccines.[166,167] Both these studies demonstrated greater mucosal anti-pneumococcal IgA and better protection against pneumococcal challenge after intranasal vaccination compared with subcutaneous vaccination. Similar findings were observed when systemic versus mucosal vaccination against influenza was studied in mice.[168]

There are significantly fewer studies on the pulmonary response to vaccines in humans. One study compared oral and nasal administration of a cholera toxin B subunit vaccine.[169] Nasal immunization resulted in fivefold increases in the levels of specific IgA antibodies in BAL fluid. No significant specific IgA responses were seen after oral immunization. Specific IgG antibody concentrations increased eightfold in BAL fluid in the nasally vaccinated subjects, although this was felt to be from transudation from serum rather than local production. Several studies have examined systemic and salivary pneumococcal-specific antibody titers after systemic vaccination in children. Infants given the 7-valent conjugated pneumococcal vaccine at 1, 2, and 3 months followed by the 23-valent polysaccharide vaccine at 9 months developed significant IgG and IgA titers in saliva up to 18 months of age.[170] Other investigators have shown that salivary anti-pneumococcal IgA, especially IgA1, can persist for 4 to 5 years in saliva after vaccination;[171] interestingly in this study, there was no difference in antibody titers between vaccinated and unvaccinated children at this time point, suggesting that natural environmental exposure also results in mucosal immunity. Finally, immunization with the pneumococcal polysaccharide vaccine has been shown to lead to an increase in salivary pneumococcal-specific IgG and IgA in adults as well.[172]

In total, these studies suggest that in general systemic vaccination induces primarily an IgG response whereas mucosal vaccination induces primarily an IgA response (Fig. 22-6). While it is clear systemic immunization can result in some local lung IgA production, the strongest mucosal immunity is induced when antigen is introduced directly into the respiratory tract. Intranasal and inhaled vaccines offer advantages in addition to the potential for improved local immunity, including the ability to immunize large populations at less cost.[173] However, despite all the theoretical benefits of mucosal vaccination, systemic vaccination remains the most prominent form today for several reasons.[174] First, mucosal vaccines typically require far greater amounts of antigen to ensure adequate absorption, and amounts needed vary by mucosal site.[175] Thus, production and quality control become more difficult. Second, mucosal vaccines are frequently live attenuated forms of the original pathogen. As such, they have the potential either to cause disease in immunosuppressed subjects or subjects with immature immune systems, as is the case for the inactivated influenza vaccine,[176] or to mutate and cause vaccine strain–related disease, as is the case for the oral poliovirus vaccine.[177] Finally, while mucosal vaccination can prevent disease at mucosal sites, it is often site-specific and potentially less effective at preventing systemic disease.[178]

Vaccination Against Pneumococcal Disease

There are currently two active vaccines against pneumococcal disease: the 23-valent pneumococcal polysaccharide vaccine (23-PPV) and the 13-valent pneumococcal conjugate vaccine. Because the conjugated vaccine contains protein linked to various polysaccharides, it is theoretically more immunogenic by virtue of its ability to induce T cell help for antibody secretion. The 23-PPV comprises capsular polysaccharide from 23 of the 92 serotypes of *Streptococcus pneumoniae*. Cross-reactivity between serogroups and the epidemiology of disease suggest that this vaccine should be effective against 80% to 90% of strains world-wide.[179] Interestingly, there is some suggestion that active vaccination strategies that reduce carriage of vaccine component serotypes may lead to replacement by nonvaccine serotypes, thereby reducing vaccine coverage.[180,181] In a recent study the 23-valent and 13-valent pneumococcal vaccines covered only 66% and 56.8%, respectively, of pneumococcal serotypes isolated from patients with pneumococcal pneumonia.[182]

While many studies suggest the pneumococcal vaccine is effective in reducing the morbidity and mortality of pneumococcal disease,[183–185] this is not a universal finding. Some studies and meta-analyses suggest the benefit is modest at most and most evident in preventing severe disease.[186–188] There are likely many reasons for these discrepant studies. Certainly study endpoints are important, and several studies suggest that pneumococcal vaccination is more effective in preventing severe systemic disease than pneumonia.[186,187] This is not surprising given the discussion above on vaccine delivery and subsequent immune responses. Since current pneumococcal vaccines are administered intramuscularly, one would predict they have greater protection against severe systemic disease than pneumonia or colonization, which is more responsive to mucosal vaccination strategies. Second, given the changing nature of serotype coverage in different parts of the world, it is likely that in some negative studies pneumococcal disease was being
